Preface to the sixth edition

There have been important developments in public health over the last decade, and these are reflected in the focus of this new edition of the *Oxford Textbook of Public Health*. There has been a dramatic decline in infant mortality and a commensurate increase in life expectancy, but at the same time, the disparities in health between rich and poor countries and between rich and poor within countries have increased. As life expectancy has increased in most regions of the world, so has the number of years individuals spend with significant disabilities from illnesses as reflected in higher disability-adjusted life years. The response to HIV/AIDS has forged new alliances between industry and public health and demonstrated the potential synergy between treatment and prevention approaches for control of infectious diseases. The speed of transmission of severe acute respiratory syndrome (SARS) in 2003 and the recent influenza epidemics which spread across continents within weeks have underscored the interdependency of nations, the need for international cooperation and the development of international and cross-border surveillance and control programs. The epidemic of chronic diseases has spread to middle- and low-income countries which now have the majority of cancer, diabetes, and heart disease occurring globally. Urbanization is occurring at an unprecedented rate and scale in rapidly emerging economies, bringing many new health and social challenges. These events, trends, and programs are rapidly changing the scope, reach, and character of public health.

Since the publication of the last edition it has become increasingly clear that public health must adopt a global perspective in assessing needs, developing interventions and ensuring good governance (Chapters 1.5, 11.13). This is underscored by the decision of the editors to change the title of the textbook to the *Oxford Textbook of Global Public Health* which better reflects the scope of the book and the issues covered in it. To capture this new perspective, we have updated all the chapters, added new chapters and recruited new authors with particular expertise in the rapidly changing scope and responsibilities of public health.

Global health problems of the 21st century

The development of real-time communication systems, rapid global travel and the pervasive use of the social media has had a huge impact on health and disease (Chapter 4.3). The outbreak of SARS, which began in Guangdong province in China in late 2002 and

from Hong Kong, spread across the world in days to weeks underscores the rapidity with which epidemics can develop in the 21st century and the consequent challenges of controlling their rapid spread. The evolution of the internet while proving to be a useful tool in the control of disease through information sharing and dissemination of preventive and control strategies, has also greatly enabled activities that are detrimental to public health such as the sale of counterfeit drugs, propagation of misinformation about disease and strategies to control disease and spreading sexually transmitted diseases through websites facilitating sexual liaisons.

Chronic diseases have now overtaken infectious diseases as the major global health problem even in developing countries (Chapters 8.1–8.6). Developing countries must now face the dual challenge of rapidly increasing incidence of chronic diseases and the persistence of infectious diseases, many of which are becoming resistant to available drugs e.g. for tuberculosis, malaria, gonorrhea, etc. Many countries are now experiencing an epidemic of diabetes and obesity related to changing lifestyles associated with increasing prosperity.

As the physical health of the global population has generally improved, there has been growing awareness of the increasing prevalence of mental illness, especially depression, a leading cause of morbidity and non-productivity (Chapter 8.7). Concomitant with the increasing prevalence of mental illness, there has been an increase of overtreatment with anti-depressants and other drugs for mental illness which introduce drug-related problems. Overuse and abuse of anti-microbial drugs has also promoted the emergence of drug-resistant organisms. For a number of infectious diseases, there remains only one effective drug and in some cases, no effective drug leaving the population vulnerable to infections which had previously been considered to be under control.

Globalization has spurred internal migration of rural poor to urban centers, especially in developing countries, overwhelming the ability of cities to provide essential services such as clean water and safe disposal of waste (Chapters 1.5, 2.7, 6.2, 9.7, 10.1). Crowding in slums created by these migrants promotes the rapid spread of many infectious diseases, a hazard to all segments of the urban population. Internal migration also often leads to the break up of the family structure as it is the male who is more likely to migrate causing social disruption and the loss of the main social support system and social safety net in many developing countries.

Globalization has also been associated with the rapid development of industrialization and a steep increase in the number of vehicles, both of which have caused a severe increase in air and water pollution which in turn has increased the rate of climate change and its associated problems. The steep rise in water and air pollution and the impact of these on climate change transcend national boundaries and will require not only more comprehensive national responses but also greater international cooperation (Chapters 7.1–7.5).

Violence, only recently recognized as being in the sphere of public health, has been increasing in many parts of the world (Chapters 9.5, 9.6). The root causes of violence involve social inequality and the lack of access by much of the world's poor to basic social, economic and health resources. Thus, inequality, both between nations and within nations, a fundamental cause of the failure of many to attain the basic human right of good health, also affects the quality of life through promotion of violence. Although inequality is basically a political issue, public health must also play a role in reducing inequality (Chapters 2.2, 3.3). A component of this inequality affecting health is the lack of health professionals in both developing and developed countries (Chapter 11.9). Developing countries are effectively subsidizing the health of developed countries, as many of their citizens trained as healthcare professionals migrate to the more attractive positions offered in developed countries exacerbating the problem of health inequality suffered by developing countries.

Strategies to address public health problems in the 21st century

Traditionally public health professionals have relied on death rates, including infant mortality rates, to gauge the health status of a country. However, many diseases including mental illness and accidents impact the ability of individuals to function without necessarily increasing their probability of dying. The development of new metrics such as disability adjusted life years, years of healthy life lost and other strategies has provided important new ways to estimate the impact of these non-fatal diseases on health and the ability of individuals to function to their full potential (Chapter 5.17). The estimates developed from these strategies have contributed greatly to our ability to characterize health problems and to prioritize limited health resources to address key issues.

The 20th century also witnessed a rapid development of new technologies, including more sensitive approaches to identify genetic determinants of disease (Chapter 2.5). These technologies have been put in the service of public health and will play an increasingly role in the future. However, the development and application of these new technologies to assess health and to identify those at risk of disease also raise serious ethical issues (Chapter 3.2).

Surveillance has been an essential tool to monitor the magnitude and spread of disease in human and animal populations (Chapter 5.19). The increasing recognition that disease agents do not respect national boundaries and that emerging infectious diseases can spread between continents within days to weeks has highlighted the need to strengthen international surveillance strategies and cooperation to provide early warning of emerging and re-emerging health threats such as pandemic influenza so that more timely and effective strategies for containment can be implemented (Chapter 3.2).

The late 20th and early 21st centuries have witnessed the increasing commitment of some sections of the private sector to the health of the public as part of their corporate responsibility (Chapter 11.12). The private sector now plays a significant role in international public health through the contribution of pharmaceutical and other companies and foundations supported by the private sector such as the Ford Foundation, the Rockefeller Foundation and more recently the Gates Foundation. While it is clear that they can play a significant role in promoting health, it is crucial that they recognize the importance of working with developing countries in developing their health agendas so as to maximize their impact. The development of guidelines for health assistance such as those put forth in the Paris Declaration on Aid Effectiveness (2005), the Accra Agenda for Action (2008) and the International Health Partnership and Related Initiatives (2007) provide guidance for the private sector to maximize the contributions to international public health (Chapter 11.13).

The United Nations has spurred the contribution of developed countries to international health through the creation of the Global Fund to Fight AIDS, Tuberculosis and Malaria. This has been augmented by national bilateral and multilateral funds such as the US President's Emergency Plan for AIDS Relief and the programs of the European Union. These programs have made significant contributions to control of disease and promotion of global health.

The costs of drugs, protected by international trade and patent agreements, have been a major barrier to the control of such diseases as HIV/AIDS. Recently, however, pharmaceutical companies have been providing these drugs to developing countries at affordable prices and through outright donations (Chapter 8.3).

Public health challenges in the 21st century

The problems cited above persist in the 21st century, and will require international cooperation, research and public health action to address effectively. Many of the preventable infectious diseases have been brought under control through immunization programs although not eradicated (Chapters 8.11, 11.3, 11.4). Eradication of polio is within sight, but political issues in Pakistan and Nigeria have been associated with the killing of vaccinators, presenting a difficult problem not easily addressed by strategies available to public health.

Drug resistance will be an increasing problem that transcends national boundaries. New drugs need to be developed rapidly, but the issue of misuse of drugs, the cause of developing resistance to many drugs, needs to be urgently addressed as well (Chapters 8.12–8.15).

Although many infectious diseases have been brought under control, that control is very fragile and dependent on continued vigilance. Complacency is perhaps the worst enemy of vigilance undermining the considerable effort necessary to assure continued control of these preventable diseases (Chapter 11.13).

The epidemics of obesity and diabetes and the continuing problems of cardiovascular diseases and cancer need to be addressed in the 21st century (Chapters 8.1 and 8.2). This will be a particular challenge as it primarily involves changes in lifestyle from a sedentary existence requiring little effort to engaging in physical activities, changing eating habits and modifying many comfortable

habits to which the public have become accustomed (Chapter 6.4). Prevention of chronic diseases requires taking personal responsibility for one's health. It is the job of public health to promote the assumption of that responsibility by the public (Chapter 8.4).

As rates of infant mortality have declined markedly in the late 20th century and duration of life has been extended, the population of the world is aging (Chapter 6.3). Thus the ratio of the productive age individuals to dependent age individuals has declined. Hence, a shrinking working age population will be responsible for supporting an increasing population of elderly. Increased worker productivity will be key to sustaining and improving the economic well-being of the global population. Increased health and the ability to function at full capacity will be key factors for increasing worker productivity and are the responsibility of public health (Chapters 3.1, 10.8). However, youth are increasingly vulnerable to drugs, violence, poverty, the changing make-up of the family, and mental health problems, exacerbated by increasing economic disparities between rich and poor globally and nationally (Chapters 8.7, 9.2, 9.5, 10.1, 10.4).

The world needs to ensure universal coverage of affordable health care and to increase the investment in the development and training of health professionals who will lead the essential public health initiatives of the 21st century. Distribution of this health workforce must be more equal and part of an effort to reduce health and social disparities (Chapters 2.2–2.4 and 11.3).

Recently there has been greater recognition of the need to scale up the effective implementation of strategies that have been

demonstrated through research to improve health. Thus, the field of 'implementation science', which deals with issues of how to bring effective strategies to a scale which will impact the health of the public, has gained prominence as an important research thrust (Chapters 6.3, 6.4).

The sixth edition of the *Oxford Textbook of Global Public Health*

It is the intention of this 6th edition of the *Oxford Textbook of Global Public Health* to provide comprehensive insights into global health problems now and in the future, and to present strategies and initiatives to address these problems. Although public health professionals will agree on the problems that need to be addressed, there is a diversity of opinions on the optimal approaches to tackle them. It is also our intention to review the diversity of these opinions and to present our views and those of our expert contributors on the merits and shortcomings of these proposed strategies.

The 6th edition, as with previous editions, is targeted primarily at public health professionals, particularly those entering the field who wish to learn about the scope and diversity of global public health. Public health is an exciting field in which to work and has the ability and potential to substantially improve the health of millions of people all over the world. Above all, it is our intention to convey the excitement and the power of public health to promote 'health for all' through this 6th edition.

Introduction to Volume 1: The scope of public health

The scope of public health is vast and continues to evolve rapidly, seeking to address the daunting challenges to health in the twenty-first century while seizing new opportunities for advancing the well-being of the peoples of the world. From an earlier focus on population health, it has grown to encompass a greater emphasis on equity as encapsulated by the World Health Organization's goal of 'health for all' and, more recently, expanded into the concept of global health in recognition of the profound impact of globalization on health and its determinants. Volume 1 of the 6th edition of the *Oxford Textbook of Global Public Health* traces the salient aspects of this evolution for countries at different stages of development, and provides in-depth overviews of long-standing as well as emerging issues of critical importance within the broad scope of public health.

Volume 1 maps the breadth of public health through three fully updated sections, namely, the history and development of public health; determinants of health and disease; and public health policies, law and ethics.

Section 1 sets the broad context and framework with Chapter 1.1 providing a high-level overview of contemporary health issues and the expanded functions of public health. The three chapters that follow describe how history, the phase of economic development and regional particularities have influenced the contours and directions of public health development in rich, low- and middle-income, and emerging economies respectively. All these countries, however, are experiencing the immense and growing impact of globalization on health and its determinants. Chapter 1.5 reviews the major forces and drivers associated with a much more globalized world, and the complex and varied influences that these are exerting on health and healthcare systems in different geographies. To respond adequately to these new challenges and dynamics, a much higher extent and depth of international coordination and cooperation across many sectors will be required.

These considerations set the essential backdrop for Section 2 which covers the determinants of health and disease, the thorough understanding of which is crucial to the development of effective and sustainable long-term interventions for public health problems. Chapter 2.1 provides a new overview of the determinants of health, emphasizing their complexity and inter-relatedness. A new

chapter on poverty, justice and health (Chapter 2.2) discusses the meaning of justice as applied to health and focuses on factors that contribute to social inequities in health in both developed and resource-constrained countries. These issues are taken up in detail in the following chapters on socio-economic inequalities in health in high-income countries (Chapter 2.3), and reducing health inequalities in developing countries (Chapter 2.4).

Beyond the social determinants of health and disease, dramatic advances in genomics research are providing new insights into the causes and pathogenesis of diseases, and their genetic determinants. The application of genomics research techniques to public health and epidemiology, a topic covered in Chapter 2.5, also offers the potential for better designed public health programmes as well as more accurate stratification of sub-populations and individuals at significantly increased risk of specific diseases, raising the prospect for targeted public health interventions.

The chapters that follow provide updated reviews of long-standing public health concerns which remain critically important, namely water and sanitation; nutrition and food safety; and the environment with a strengthened focus on the public health impact of climate change. The high and rising prevalence of chronic non-communicable diseases throughout the world which have their roots in risk factors linked to lifestyles and behaviours, has led to heightened interest in the behavioural determinants of health and disease, an important subject covered in Chapter 2.9. The widespread adoption of health-promoting behaviours, at the level of individuals and societies, is arguably one of the most important challenges for public health in this century. Section 2, with its focus on social and health inequalities, is aptly rounded off with Chapter 2.10 which addresses key issues in access to healthcare, and the importance of universal coverage and equitable access to affordable and cost-effective health interventions.

The last section of Volume 1 which focuses on public health policies, law and ethics, builds on the issues and considerations discussed in the preceding sections. Section 3 starts with a discussion on the need for, and the changing forms of, leadership in public health. Chapter 3.2 considers key ethical issues in public health and the evolution of principles and guidelines for its practice and

research, while Chapter 3.3 reaffirms the commitment of public health to work towards the highest attainable standard of health. These lead up to a new chapter on the role of law and legal instruments in achieving public health objectives at the local, national and global levels. A new chapter, 3.5, reviews the complex but important issues of priority setting and rationing in public health and healthcare delivery. This is followed by discussion of the major drivers, forms and directions of health policy formulation and implementation in developing countries and developed countries, in Chapters 3.6 and 3.7 respectively. Given the high and growing interconnectedness of our world, and the powerful and pervasive impact of globalization on health and disease, Chapter 3.8

describes the importance of greater international collaboration and coordinated action, and the efforts jointly required and taken to promote public health in countries across the world.

The extensive responsibilities and the varied and changing scope of public health described in this volume will require public health policy-makers and professionals to work closely together across a wide range of disciplines, to establish intersectoral partnerships and international coalitions that encompass the public, not-for-profit and private sectors, and, most importantly, to engage communities to achieve the goals of improving population health and promoting equity for all, so as to realise the full promise of public health for the 21st century.

SECTION 10**Public health needs of population groups****10.1 The changing family 1317**

Gavin W. Jones

10.2 Women, men, and health 1328

Sarah Payne and Lesley Doyal

10.3 Child health 1344Cynthia Boschi-Pinto, Nigel Rollins, Bernadette Daelmans,
Rajiv Bahl, Jose Martines, and Elizabeth Mason**10.4 Adolescent health 1359**Pierre-André Michaud, Anne-Emmanuelle Ambresin,
Richard F. Catalano, Judith Diers, and Georges C. Patton**10.5 Ethnicity, race, epidemiology, and public health 1371**

Raj Bhopal

10.6 The health of indigenous peoples 1382

Ian Anderson and Sue Crengle

10.7 People with disabilities 1392

Donald J. Lollar and Elena M. Andresen

10.8 Health of older people 1408

Julie E. Byles and Meredith A. Tavener

10.9 Forced migrants and other displaced populations 1425

Catherine R. Bateman Steel and Anthony B. Zwi

10.10 Prisons: from punishment to public health 1445

Ernest Drucker

SECTION 11**Public health functions****11.1 Health needs assessment 1463**

Michael P. Kelly, Jane E. Powell, and Natalie Bartle

11.2 Prevention and control of non-communicable diseases 1476

K. Srinath Reddy

11.3 Principles of infectious disease control 1484

Robert J. Kim-Farley

11.4 Population screening and public health 1507

Allison Streetly and Lars Elhers

11.5 Environmental health practice 1523

Yasmin E.R. von Schirnding

11.6 Strategies and structures for public health intervention 1542

Sian Griffiths

11.7 Strategies for health services 1563

Chien Earn Lee

- 11.8 Training of public health professionals in developing countries** 1580
Vonthanak Saphonn, San Hone, and Roger Detels
- 11.9 Training of local health workers to meet public health needs** 1585
Piya Hanvoravongchai and Suwit Wibulpolprasert
- 11.10 Emergency public health and humanitarian assistance in the twenty-first century** 1594
Les Roberts and Richard Brennan
- 11.11 Principles of public health emergency response for acute environmental, chemical, and radiation incidents** 1608
Naima Bradley, Jill Meara, and Virginia Murray

List of Contributors

Quarraisha Abdool Karim Associate Scientific Director, CAPRISA; Professor in Epidemiology, Columbia University, USA; Adjunct Professor in Public Health and Family Medicine, University of KwaZulu-Natal, South Africa
Chapter 11.12 Private support of public health

Maia Ambegaokar Principal, Health Governance, Policy Planning Management consultancy, Sydney, Australia
Chapter 3.1 Leadership in public health

Anne-Emmanuelle Ambresin Senior Resident, Multidisciplinary Unit for Adolescent Health, University Hospital/CHUV, Lausanne, Switzerland
Chapter 10.4 Adolescent health

Ian Anderson Murrup Barak, Melbourne Institute for Indigenous Development, The University of Melbourne, Melbourne, VIC, Australia
Chapter 10.6 The health of indigenous peoples

Elena M. Andresen Interim Dean, Public Health, Oregon Health & Science University, and Portland State University, Portland, OR, USA
Chapter 10.7 People with disabilities

Tar-Ching Aw College of Medicine and Health Sciences, United Arab Emirates University, Al Ain, United Arab Emirates
Chapter 7.4 Occupational health
Chapter 7.5 Toxicology and risk assessment in the analysis and management of environmental risk

Gunilla Backman Swedish International Development Cooperation Agency, Stockholm, Sweden
Chapter 3.3 The right to the highest attainable standard of health

Rajiv Bahl World Health Organization, Geneva, Switzerland
Chapter 10.3 Child health

Lope H. Barrero Department of Industrial Engineering, Pontificia Universidad Javeriana, Bogotá, Colombia
Chapter 8.9 Musculoskeletal diseases

Natalie Bartle NHS Trust Development Authority, Midlands and East, UK
Chapter 11.1 Health needs assessment

Catherine R. Bateman Steel School of Social Sciences at the University of New South Wales, Sydney, NSW, Australia
Chapter 10.9 Forced migrants and other displaced populations

Frances Baum Director of the Southgate Institute of Health, Society and Equity at Flinders University, Adelaide, SA, Australia
Chapter 2.2 Poverty, justice, and health

Yoav Ben-Shlomo School of Social and Community Medicine, University of Bristol, Bristol, UK
Chapter 5.20 Life course epidemiology and analysis

Douglas Bettcher Director, Prevention of Noncommunicable Diseases, World Health Organization, Geneva, Switzerland
Chapter 3.8 International efforts to promote public health

Raj Bhopal Edinburgh Ethnicity and Health Research Group, University of Edinburgh, Edinburgh, UK
Chapter 10.5 Ethnicity, race, epidemiology, and public health

Zulfiqar A. Bhutta Robert Harding Chair in Global Child Health & Policy, Centre for Global Child Health, Hospital for Sick Children Toronto, Canada; Founding Director, Centre of Excellence in Women & Child Health, The Aga Khan University, Karachi, Pakistan
Chapter 8.11 Infectious diseases and prions

Marieke Boezen University of Groningen, University Medical Center Groningen, Department of Epidemiology, Groningen, Netherlands
Chapter 8.3 Chronic obstructive pulmonary disease and asthma

Paolo Boffetta Director of the Institute for Translational Epidemiology at Mount Sinai Hospital, New York, NY, USA
Chapter 8.2 Cancer epidemiology and public health

Chris Bonell Department of Childhood, Families and Health, Institute of Education, University of London, UK
Chapter 6.5 Development and evaluation of complex multicomponent interventions in public health

Cynthia Boschi-Pinto World Health Organization, Geneva, Switzerland; and Universidade Federal Fluminense, Niterói, Brazil
Chapter 10.3 Child health

- James Bowen** Medical Director, Multiple Sclerosis Center, Swedish Neuroscience Institute, Seattle, WA, USA
Chapter 8.10 Neurological diseases, epidemiology, and public health
- Naima Bradley** Public Health England, Chilton, UK
Chapter 11.11 Principles of public health emergency response for acute environmental, chemical, and radiation incidents
- Richard Brennan** World Health Organization, Geneva, Switzerland
Chapter 11.10 Emergency public health and humanitarian assistance in the twenty-first century
- Benjamin Bristow** Mount Sinai Global Health, Icahn School of Medicine at Mount Sinai, New York, NY, USA
Chapter 8.15 Malaria
- Collin Brooks** Centre for Public Health Research, Massey University, Wellington, New Zealand
Chapter 8.3 Chronic obstructive pulmonary disease and asthma
- James W. Buehler** Health Management and Policy, School of Public Health, Drexel University, Philadelphia, PA, USA
Chapter 5.19 Public health surveillance
- Wylie Burke** Department of Bioethics and Humanities, University of Washington, Seattle, WA, USA
Chapter 2.5 Genomics and public health
- Julie E. Byles** Research Centre for Gender, Health and Ageing, at the University of Newcastle, Callaghan, NSW, Australia
Chapter 10.8 Health of older people
- Alberto J. Caban-Martinez** Department of Environmental Health, Harvard University School of Public Health, Boston, MA, USA
Chapter 8.9 Musculoskeletal diseases
- Rona Campbell** Director of the Centre for the Development and Evaluation of Complex Interventions for Public Health Improvement—DECIPHer, School for Social and Community Medicine, University of Bristol, UK
Chapter 6.5 Development and evaluation of complex multicomponent interventions in public health
- Simon Carroll** Community Health Promotion Research Centre, University of Victoria, BC, Canada
Chapter 6.4 Health promotion, health education, and the public's health
- Richard F. Catalano** Richard E. Chaisson, Johns Hopkins University School of Medicine and Bloomberg School of Public Health, Baltimore, MD, USA
Chapter 10.4 Adolescent health
- Richard E. Chaisson** Johns Hopkins University, School of Medicine and Bloomberg School of Public Health, Baltimore, MD, USA
Chapter 8.14 Tuberculosis
- Margaret Chan** World Health Organization, Geneva, Switzerland
Chapter 11.13 The future of international public health in an era of austerity
- Leda Chatzi** Department of Social Medicine, Medical School, University of Crete, Heraklion, Greece
Chapter 5.3 Cross-sectional studies
- Chien-Jen Chen** Graduate Institute of Epidemiology, National Taiwan University College of Public Health, Taipei, Taiwan
Chapter 7.1 Environmental health issues in public health
- Peter Cherutich** National AIDS & STI Control Programme—NASCOP, Kenyatta National Hospital Grounds, Nairobi, Kenya
Chapter 4.2 Information systems and community diagnosis in low- and middle-income countries
- Gavin J. Churchyard** Aurum Institute NPC, Johannesburg, Gauteng, South Africa
Chapter 8.14 Tuberculosis
- Sarah Clark** School of Public Policy at the Department of Political Science, University College London, London, UK
Chapter 3.5 Priority setting, social values, and public health
- Mike Clarke** Director of the MRC Hub for Trials Methodology Research at the Centre for Public Health, Queens University Belfast, Belfast, UK
Chapter 5.15 Systematic reviews and meta-analysis
- Thomas Clasen** Professor of Environmental Health, Rollins School of Public Health, Emory University, Atlanta, GA, USA; Reader in Water, Sanitation and Health, London School of Hygiene & Tropical Medicine, London, UK
Chapter 2.6 Water and sanitation
- Hoosen Coovadia** MatCH (Maternal Adolescent and Child Health) at the University of Witwatersrand, Nelson R. Mandela School of Medicine, Doris Duke Medical Research Institute, Durban, South Africa
Chapter 2.4 Reducing health inequalities in developing countries
- Sue Crengle** Senior Lecturer, Te Kupenga Hauora Maori, School of Population Health, University of Auckland, Auckland, New Zealand
Chapter 10.6 The health of indigenous peoples
- Bernadette Daelmans** World Health Organization, Geneva, Switzerland
Chapter 10.3 Child health
- Julia Dalzell** Program Director at the Center for Food Law and Policy, Los Angeles, CA, USA
Chapter 3.8 International efforts to promote public health
- Manuel M. Dayrit** Dean, Ateneo School of Medicine and Public Health, Ateneo de Manila University, Philippines
Chapter 3.1 Leadership in public health
- Katherine DeLand** World Health Organization, Geneva, Switzerland
Chapter 3.8 International efforts to promote public health

- Don Des Jarlais** The Baron Edmond de Rothschild Chemical Dependency Institute, Beth Israel Medical Center, New York City, NY, USA
Chapter 9.2 Public health aspects of illicit psychoactive drug use
- Roger Detels** Distinguished Professor of Epidemiology and Infectious Diseases, Schools of Public Health and Medicine, University of California, Los Angeles, CA, USA
Chapter 1.1 The scope and concerns of public health
Chapter 5.1 Epidemiology: the foundation of public health
Chapter 8.5 Physical activity and health
Chapter 11.8 Training of public health professionals in developing countries
Chapter 11.12 Private support of public health
- Nancy Devlin** Director of Research, Office of Health Economics, London, UK
Chapter 6.6 Economic appraisal in public healthcare: assessing efficiency and equity
- Judith Diers** Chief, Adolescent Development and Participation, UNICEF, New York, NY, USA
Chapter 10.4 Adolescent health
- Ana V. Diez Roux** Department of Epidemiology, University of Michigan School of Public Health, Ann Arbor, MI, USA
Chapter 5.2 Ecological variables, ecological studies, and multilevel studies in public health research
- Allan Donner** Department of Epidemiology and Biostatistics at the Schulich School of Medicine and Dentistry, University of Western Ontario, London, ON, Canada
Chapter 5.8 Methodological issues in the design and analysis of community intervention trials
- Jeroen Douwes** Centre for Public Health Research, Massey University, Wellington, New Zealand
Chapter 8.3 Chronic obstructive pulmonary disease and asthma
- David W. Dowdy** Department of Epidemiology, Johns Hopkins University, Baltimore, MD, USA
Chapter 8.14 Tuberculosis
- Lesley Doyal** Centre for Health and Social Care at the School for Policy Studies, University of Bristol, Bristol, UK
Chapter 10.2 Women, men, and health
- Ernest Drucker** Director of the Division of Public Health and Policy Research, Montefiore Medical Center, Albert Einstein College of Medicine, New York, NY, USA
Chapter 10.10 Prisons: from punishment to public health
- Mohan J. Dutta** Brian Lamb School of Communication, Purdue University, West Lafayette, IN, USA
Chapter 4.3 New communication technologies, social media, and public health
- Lars Elhers** Danish Center for Healthcare Improvements, Faculty of Social Science & Faculty of Health Science, Aalborg University, Aalborg, Denmark
Chapter 11.4 Population screening and public health
- John W. Farquhar** C.F. Rehnborg Professor in Disease Prevention and Professor of Medicine and Health Research and Policy, Stanford Prevention Research Center, Stanford University School of Medicine, Stanford, CA, USA
Chapter 5.9 Community intervention trials in high-income countries
- Jonathan Feelemyer** The Baron Edmond de Rothschild Chemical Dependency Institute, Beth Israel Medical Center, New York City, NY, USA
Chapter 9.2 Public health aspects of illicit psychoactive drug use
- Louise Finer** Her Majesty's Inspectorate of Prisons, London, UK
Chapter 3.3 The right to the highest attainable standard of health
- Baruch Fischhoff** Howard Heinz University Professor, Department of Social and Decision Sciences, Department of Engineering and Public Policy, Carnegie Mellon University, Pittsburgh, PA, USA
Chapter 7.6 Risk perception and communication
- Dan W. Fitzgerald** Weill Cornell Graduate School of Medical Sciences, Cornell University, New York, NY, USA
Chapter 6.9 Implementation science and translational public health
- Julio Frenk** Dean of the Faculty, T&G Angelopoulos Professor of Public Health and International Development, Harvard School of Public Health and Harvard Kennedy School, Harvard University, Boston, MA, USA
Chapter 3.6 Health policy in developing countries
- Irwin Friedman** The Health Programme of the SEED Trust, Durban, South Africa
Chapter 2.4 Reducing health inequalities in developing countries
- Lawrence M. Friedman** Independent Consultant, Rockville, MD, USA
Chapter 5.7 Methodology of intervention trials in individuals
- Jonathan Garcia** Center for the Study of Culture, Politics and Health, Department of Sociomedical Sciences, Mailman School of Public Health, Columbia University, New York City, NY, USA
Chapter 6.2 Sexuality and public health
- Patricia J. Garcia** Dean, School of Public Health and Administration (FASPA), Universidad Peruana Cayetano Heredia (UPCH), Lima, Peru
Chapter 8.12 Sexually transmitted infections
- Bernard D. Goldstein** Dean Emeritus, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA
Chapter 7.5 Toxicology and risk assessment in the analysis and management of environmental risk
- Octavio Gómez-Dantés** National Institute of Public Health, Cuernavaca, Mexico
Chapter 3.6 Health policy in developing countries

Miguel Angel González-Block National Institute of Public Health, Cuernavaca, Mexico
Chapter 3.6 Health policy in developing countries

Fernando Gonzalez-Martinez World Health Organization, Geneva, Switzerland
Chapter 3.8 International efforts to promote public health

Lawrence Gostin Faculty Director, O'Neill Institute for National and Global Health Law, Washington, DC; Director, WHO Collaborating Center on Public Health Law & Human Rights; Johns Hopkins University, Baltimore, MD; based at Georgetown Law, Washington, DC, USA
Chapter 3.4 Law and the public's health

Adele Green QIMR Berghofer Medical Research Institute, Brisbane, QLD; Cancer Research UK Manchester Institute, University of Manchester, Manchester, UK
Chapter 7.2 Radiation and public health

Lawrence W. Green Professor, Department of Epidemiology & Biostatistics at the University of California School of Medicine, San Francisco, CA, USA
Chapter 2.9 Behavioural determinants of health and disease
Chapter 5.9 Community intervention trials in high-income countries

Sander Greenland Department of Epidemiology, UCLA School of Public Health, Los Angeles, CA, USA
Chapter 5.13 Validity and bias in epidemiological research
Chapter 5.14 Causation and causal inference

Sian Griffiths Faculty of Medicine at the Chinese University of Hong Kong, Hong Kong
Chapter 11.6 Strategies and structures for public health intervention

Emily Grundy London School of Economics, London, UK
Chapter 6.3 Demography and public health

Martin Gulliford Department of Primary Care and Public Health Sciences, King's College London, London, UK
Chapter 2.10 Access to healthcare and population health

John Gulliver School of Public Health, Imperial College London, London, UK
Chapter 7.3 Environmental exposure assessment: modelling air pollution concentrations

Davidson H. Hamer Center for Global Health and Development, Boston University; Boston University Schools of Public Health and Medicine, Boston, MA; Tufts University Friedman School of Nutrition Science and Policy, Boston, MA, USA
Chapter 8.11 Infectious diseases and prions

Christopher Hamlin University of Notre Dame, Notre Dame, IN, USA
Chapter 1.2 The history and development of public health in developed countries

Piya Hanvoravongchai Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand
Chapter 11.9 Training of local health workers to meet public health needs

Rebecca Hardy MRC National Survey of Health and Development at the MRC Unit for Lifelong Health and Ageing at UCL, London, UK
Chapter 5.20 Life course epidemiology and analysis

Deborah Hassin Columbia University, New York City, NY, USA
Chapter 9.2 Public health aspects of illicit psychoactive drug use

David L. Heymann Chairman, Health Protection Agency, London, UK
Chapter 8.17 Emerging and re-emerging infections

Robert A. Hiatt Professor and Chair, Department of Epidemiology & Biostatistics at the University of California School of Medicine, San Francisco, CA, USA
Chapter 2.9 Behavioural determinants of health and disease

Marcia Hills Community Health Promotion Research Centre, University of Victoria, BC, Canada
Chapter 6.4 Health promotion, health education, and the public's health

Gavin Hitchcock South African Centre for Epidemiological Modelling and Analysis (SACEMA), Stellenbosch, South Africa
Chapter 5.18 Mathematical models of transmission and control of infectious agents

Sai Yin Ho School of Public Health, The University of Hong Kong, Hong Kong
Chapter 9.1 Tobacco

Kristin S. Hoefft Department of Epidemiology & Biostatistics at the University of California School of Medicine, San Francisco, CA, USA
Chapter 2.9 Behavioural determinants of health and disease

Katherine J. Hoggatt Department of Epidemiology, UCLA School of Public Health, Los Angeles, CA, USA
Chapter 5.14 Causation and causal inference

San Hone Assistant Director, National Aids Control Program, Disease Control Complex, Department of Health, Nay Pyi Taw, Myanmar
Chapter 11.8 Training of public health professionals in developing countries

Kees de Hoogh School of Public Health, Imperial College London, London, UK
Chapter 7.3 Environmental exposure assessment: modelling air pollution concentrations

Paul Hunt School of Law, University of Essex, Colchester, UK
Chapter 3.3 The right to the highest attainable standard of health

Anne Huvos World Health Organization, Geneva, Switzerland
Chapter 3.8 International efforts to promote public health

Adnan Hyder Johns Hopkins University, Bloomberg School of Public Health, International Injury Research Unit, Baltimore, MD, USA
Chapter 9.4 Injury prevention and control: the public health approach

- Sopon Iamsirithaworn** Bureau of Epidemiology, Department of Disease Control, Ministry of Public Health, Thailand
Chapter 5.4 Principles of outbreak investigation
- Richard J. Jackson** Department of Environmental Health Sciences, Fielding School of Public Health, University of California, Los Angeles, CA, USA
Chapter 2.1 Determinants of health: overview
- W. Philip T. James** London School of Hygiene and Tropical Medicine, International Association for the Study of Obesity (IASO), London, UK
Chapter 8.4 Obesity
- Rachel Jewkes** Director, MRC Gender & Health Research Unit, South African Medical Research Council, Pretoria, South Africa
Chapter 9.5 Interpersonal violence: a recent public health mandate
- Gavin W. Jones** Director, J. Y. Pillay Comparative Asia Research Centre, Singapore
Chapter 10.1 The changing family
- Mary L. Kamb** Associate Director for Global Activities, Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD and TB Prevention, US Centers for Disease Control and Prevention, Atlanta, GA, USA
Chapter 8.12 Sexually transmitted infections
- Nancy Kass** Johns Hopkins Berman Institute of Bioethics and Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA
Chapter 3.2 Ethical principles and ethical issues in public health
- Nicholas S. Kelley** Center for Infectious Disease Research and Policy, University of Minnesota, Minneapolis, MN, USA
Chapter 8.18 Bioterrorism
- Michael P. Kelly** The Institute of Public Health, University of Cambridge, Cambridge, UK
Chapter 11.1 Health needs assessment
- Judd B. Kessler** Business Economics and Public Policy Department, The Wharton School, University of Pennsylvania, Philadelphia, PA, USA
Chapter 6.7 Behavioural economics and health
- Leeka Kheifets** Department of Epidemiology at UCLA School of Public Health, Los Angeles, CA, USA
Chapter 7.2 Radiation and public health
- Rajat Khosla** World Health Organization, Geneva, Switzerland
Chapter 3.3 The right to the highest attainable standard of health
- Muin J. Khoury** Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA, USA
Chapter 2.5 Genomics and public health
- Ann Marie Kimball** Bill and Melinda Gates Foundation, Seattle, WA, USA
Chapter 5.19 Public health surveillance
- Robert J. Kim-Farley** Director, Communicable Disease Control and Prevention, Los Angeles County Department of Public Health; Fielding School of Public Health, University of California, Los Angeles, CA, USA
Chapter 11.3 Principles of infectious disease control
- Mary Kay Kindhauser** World Health Organization, Geneva, Switzerland
Chapter 11.13 The future of international public health in an era of austerity
- Bartha M. Knoppers** Director, Centre of Genomics and Policy, Canada Research Chair in Law and Medicine, Faculty of Medicine, Department of Human Genetics, McGill University, Montreal, Quebec, Canada
Chapter 2.5 Genomics and public health
- Manolis Kogevinas** Centre for Research in Environmental Epidemiology (CREAL), Barcelona, Spain; IMIM (Hospital del Mar Medical Research Institute), Barcelona, Spain; CIBER Epidemiologia y Salud Pública (CIBERESP), Spain; and National School of Public Health, Athens, Greece
Chapter 5.3 Cross-sectional studies
- David Koh** Assistant Vice-Chancellor, Vice-President and Chair Professor, Universiti Brunei Darussalam, Brunei; Professor, Saw Swee Hock School of Public Health, National University of Singapore, Singapore
Chapter 7.4 Occupational health
Chapter 7.5 Toxicology and risk assessment in the analysis and management of environmental risk
- Dragana Korljan** UN Office of the High Commissioner for Human Rights, Geneva, Switzerland
Chapter 3.3 The right to the highest attainable standard of health
- Diana Kuh** MRC National Survey of Health and Development at the MRC Unit for Lifelong Health and Ageing at UCL, London, UK
Chapter 5.20 Life course epidemiology and analysis
- Walter A. Kukull** Director, National Alzheimer's Coordinating Center (NACC), Department of Epidemiology, University of Washington, Seattle, WA, USA
Chapter 8.10 Neurological diseases, epidemiology, and public health
- Ronald Labonté** Canada Research Chair and Globalization/Health Equity; Faculty of Medicine, University of Ottawa, Ottawa, ON, Canada
Chapter 2.2 Poverty, justice, and health
- Tai Hing Lam** School of Public Health, The University of Hong Kong, Hong Kong
Chapter 9.1 Tobacco
- Carlo La Vecchia** Professor of Epidemiology, Department of Clinical Sciences and Community Health, University of Milan, Italy
Chapter 8.2 Cancer epidemiology and public health
- Chien Earn Lee** Chief Executive Officer, Changi General Hospital; Saw Swee Hock School of Public Health, Singapore
Chapter 11.7 Strategies for health services

Hin-Peng Lee Saw Swee Hock School of Public Health, National University of Singapore, Singapore
Chapter 1.4 Development of public health in economic transition: the middle-income countries

Kelley Lee Director of Global Health and Associate Dean, Research Faculty of Health Sciences, Simon Fraser University, Burnaby, BC, Canada
Chapter 1.5 Globalization

Vernon J. M. Lee Saw Swee Hock School of Public Health, National University of Singapore, Singapore
Chapter 8.17 Emerging and re-emerging infections

Tinne Lernout Centre for the Evaluation of Vaccination, Vaccine & Infectious Disease Institute, Faculty of Medicine and Health Sciences, University of Antwerp, Antwerp, Belgium
Chapter 8.16 Chronic hepatitis and other liver disease

Barry S. Levy Department of Public Health and Community Medicine at Tufts University School of Medicine, Boston, MA, USA
Chapter 9.6 Collective violence: war

Gemma Lien Public Health England, London, UK
Chapter 3.8 International efforts to promote public health

Peter Littlejohns Department of Primary Care & Public Health Sciences at King's College London, London, UK
Chapter 3.5 Priority setting, social values, and public health

Donald J. Lollar Professor, Public Health and Preventive Medicine, Oregon Health & Science University, Portland, OR, USA
Chapter 10.7 People with disabilities

Adetokunbo Lucas Department of Global Health and Population, Harvard School of Public Health, Harvard University, Boston, MA, USA
Chapter 3.6 Health policy in developing countries

Johan P. Mackenbach Department of Public Health, Erasmus MC, University Medical Center, Rotterdam, Netherlands
Chapter 2.3 Socioeconomic inequalities in health in high-income countries: the facts and the options

Alex Macmillan School of Population Health, University of Auckland, Auckland, New Zealand
Chapter 2.8 The environment and climate change

Rui T. Marinho Gastroenterology department, Hospital de Santa Maria, Portugal
Chapter 8.16 Chronic hepatitis and other liver disease

Tim Marsh UK Health Forum, London, UK
Chapter 8.4 Obesity

Zoe Marshman Dental Public Health, School of Clinical Dentistry, Sheffield University, Sheffield, UK
Chapter 8.8 Dental public health

Jose Martines Centre for Intervention Science in Maternal and Child Health, Centre for International Health, University of Bergen, Norway
Chapter 10.3 Child health

Elizabeth Mason Institute for Global Health, University College London, UK. Formerly World Health Organization, Geneva, Switzerland
Chapter 10.3 Child health

Kedar S. Mate Country Director, IHI South Africa Program at the Institute for Healthcare Improvement, Cambridge, MA; Department of Medicine, Division of Hospital Medicine, Cornell University, New York, NY, USA
Chapter 6.9 Implementation science and translational public health

Jill Meara Public Health England, Chilton, UK
Chapter 11.11 Principles of public health emergency response for acute environmental, chemical, and radiation incidents

Judith Bueno de Mesquita Human Rights Centre, School of Law, University of Essex, Colchester, UK
Chapter 3.3 The right to the highest attainable standard of health

Pierre-André Michaud Chief, Multidisciplinary Unit for Adolescent Health University Hospital/CHUV, Lausanne, Switzerland
Chapter 10.4 Adolescent health

Mark R. Montgomery Senior Associate of the Population Council, New York, NY; Professor of Economics, Stony Brook University, Stony Brook, NY, USA
Chapter 9.7 Urban health in low- and middle-income countries

Stephen Morris Chair of Health Economics, Epidemiology & Public Health, Institute of Epidemiology & Health, University College London, London, UK
Chapter 6.6 Economic appraisal in public healthcare: assessing efficiency and equity

Alvaro Muñoz Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA
Chapter 5.6 Cohort studies

Miguel Muñoz-Laboy School of Social Work, College of Health Professions and Social Work, Temple University, Philadelphia, PA, USA
Chapter 6.2 Sexuality and public health

Michael Murphy London School of Economics, London, UK
Chapter 6.3 Demography and public health

Christopher J. L. Murray Director, Institute for Health Metrics and Evaluation, University of Washington, Seattle, WA, USA
Chapter 5.17 Measuring the health of populations: the Global Burden of Disease study methods

Virginia Murray Public Health England, London, UK
Chapter 11.11 Principles of public health emergency response for acute environmental, chemical, and radiation incidents

Ruth Nduati School of Medicine at the College of Health Sciences, University of Nairobi, Nairobi, Kenya
Chapter 4.2 Information systems and community diagnosis in low- and middle-income countries

Alfred I. Neugut Department of Epidemiology at the Mailman School of Public Health, Columbia University, New York, NY, USA

Chapter 8.2 Cancer epidemiology and public health

F. Javier Nieto Chair of the Department of Population Health Sciences, Helfaer Professor of Public Health, University of Wisconsin Medical School, Madison, WI, USA

Chapter 5.6 Cohort studies

Haik Nikogosian World Health Organization, Geneva, Switzerland

Chapter 3.8 International efforts to promote public health

Lisa Oldring UN Office of the High Commissioner for Human Rights, Geneva, Switzerland

Chapter 3.3 The right to the highest attainable standard of health

Michael T. Osterholm Center for Infectious Disease Research and Policy, Division of Environmental Health Sciences, School of Public Health; Medical School, University of Minnesota, Minneapolis, MN, USA

Chapter 8.18 Bioterrorism

Vural Özdemir School of Journalism, Faculty of Communications, Office of the Rector, Gaziantep University, Gaziantep, Turkey; School of Biotechnology, Amrita University, Kerala, India

Chapter 2.5 Genomics and public health

Tomás Pantoja Department of Family Medicine, School of Medicine, Pontificia Universidad Católica de Chile, Santiago, Chile

Chapter 5.11 Clinical epidemiology

Raymundo Paraná President of the Brazilian Society of Hepatology, Bahia, Brazil

Chapter 8.16 Chronic hepatitis and other liver disease

Richard Parker Center for the Study of Culture, Politics and Health, Department of Sociomedical Sciences, Mailman School of Public Health, Columbia University, New York City, NY, USA

Chapter 6.2 Sexuality and public health

David Parkin City University, London, UK

Chapter 6.6 Economic appraisal in public healthcare: assessing efficiency and equity

George C. Patton Centre for Adolescent Health, Murdoch Children's Research Institute, Melbourne, Australia

Chapter 10.4 Adolescent health

Amy Paul Johns Hopkins Berman Institute of Bioethics; Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

Chapter 3.2 Ethical principles and ethical issues in public health

Sarah Payne Centre for Health and Social Care, School for Policy Studies, University of Bristol, Bristol, UK

Chapter 10.2 Women, men, and health

Neil Pearce Centre for Public Health Research, Massey University, Wellington, New Zealand; Faculty of Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London, UK

Chapter 8.3 Chronic obstructive pulmonary disease and asthma

Corinne Peek-Asa University of Iowa, College of Public Health, Injury Prevention Research Center, Iowa City, IA, USA

Chapter 9.4 Injury prevention and control: the public health approach

Kai Hong Phua Lee Kuan Yew School of Public Policy, National University of Singapore, Singapore

Chapter 1.4 Development of public health in economic transition: the middle-income countries

Kevin Pottie Departments of Family Medicine and Epidemiology and Community Medicine, University of Ottawa, Ottawa, ON, Canada

Chapter 5.11 Clinical epidemiology

Jane E. Powell Professor of Public Health Economics, Department of Health and Social Science, University of the West of England, Bristol

Chapter 11.1 Health needs assessment

John Powles Department of Public Health and Primary Care, Institute of Public Health, University of Cambridge, Cambridge, UK

Chapter 3.7 Public health policy in developed countries

Stella R. Quah Duke-NUS Graduate Medical School, Singapore

Chapter 6.1 Sociology and psychology in public health

K. Srinath Reddy President of the Public Health Foundation of India, New Delhi, India

Chapter 11.2 Prevention and control of non-communicable diseases

Justin V. Remais Director, Graduate Program in Global Environmental Health, Department of Environmental Health, Rollins School of Public Health, Emory University, Atlanta, GA, USA

Chapter 2.1 Determinants of health: overview

Les Roberts Interim Director of the Program on Forced Migration and Health, Columbia University, New York City, NY, USA

Chapter 11.10 Emergency public health and humanitarian assistance in the twenty-first century

Peter G. Robinson Director of Research, School of Clinical Dentistry, Sheffield University, Sheffield, UK

Chapter 8.8 Dental public health

Nigel Rollins World Health Organization, Geneva, Switzerland

Chapter 10.3 Child health

Robin Room Melbourne School of Population and Global Health, University of Melbourne, Melbourne; Director of the Centre for Alcohol Policy Research (CAPR), Turning Point, Fitzroy, VIC, Australia; Centre for Social Research on Alcohol and Drugs, Stockholm University, Stockholm

Chapter 9.3 Alcohol

- David Sanders** People's Health Movement Director and Professor of the Public Health Programme, University of the Western Cape, Bellville, South Africa
Chapter 2.2 Poverty, justice, and health
- Manjinder S. Sandhu** Wellcome Trust Sanger Institute; Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK
Chapter 5.12 Genetic epidemiology
- Vonthanak Saphonn** Vice Director of the University of Health Sciences and Head of Research Unit, National Center for HIV, AIDS, Dermatology and STDs, Phnom Penh, Cambodia
Chapter 11.8 Training of public health professionals in developing countries
- Eleanor B. Schron** Director of Clinical Applications at the National Eye Institute, Bethesda, MD, USA
Chapter 5.7 Methodology of intervention trials in individuals
- Sara U. Schwanke Khilji** Communicable Disease Policy Research Group, London School of Hygiene and Tropical Medicine, London, UK
Chapter 1.4 Development of public health in economic transition: the middle-income countries
- Ulrike Schwerdtfeger** World Health Organization, Geneva, Switzerland
Chapter 3.8 International efforts to promote public health
- Than Sein** President, People's Health Foundation, Yangon, Myanmar
Chapter 1.3 The history and development of public health in low- and middle-income countries
- Shira Shafir** Department of Epidemiology, School of Public Health, UCLA, Los Angeles, CA, USA
Chapter 8.15 Malaria

The scope and concerns of public health

Roger Detels and Chorh Chuan Tan

Introduction to the scope and concerns of public health

There have been many definitions and elaborations of public health. The definition offered by the Acheson Report (Acheson 1988, p. 1) has been widely accepted:

Public health is the science and art of preventing disease, prolonging life, and promoting health through the organized efforts of society.

This definition underscores the broad scope of public health and the fact that public health is the result of all of society's efforts viewed as a whole, rather than that of single individuals.

In 2003, Roger Detels defined the goal of public health as:

The biologic, physical, and mental well-being of all members of society regardless of gender, wealth, ethnicity, sexual orientation, country, or political views. (cited in Detels 2009, p. 3)

This definition or goal emphasizes equity and the range of public health interests as encompassing not just the physical and biological, but also the mental well-being of society. The United Nation's Millennium Development Goals, the slogan of which is 'Health for All' (the Acheson report), and Detels' goals depict public health as being concerned with more than the mere elimination of disease and placing public health issues as a fundamental component of development.

To achieve the World Health Organization (WHO) goal of 'health for all', it is essential to bring to bear many diverse disciplines to the attainment of optimal health, including the physical, biological, and social sciences. The field of public health has adapted and applied these disciplines for the elimination and control of disease, and the promotion of health.

Functions of public health

Public health is concerned with the process of mobilizing local, state/provincial, national, and international resources to assure the conditions in which all people can be healthy (Detels and Breslow 2002). To successfully implement this process and to make health for all achievable, public health must perform the functions listed in Box 1.1.1.

Public health *identifies*, *measures*, and *monitors* health needs and trends at the community, national, and global levels through surveillance of disease and risk factor (e.g. smoking) trends. Analysis of these trends and the existence of a functioning health

information system provides the essential information for predicting or anticipating future community health needs.

In order to ensure the health of the population, it is necessary to *formulate*, *promote*, and *enforce* sound health policies to prevent and control disease, and to reduce the prevalence of factors impairing the health of the community. These include policies requiring reporting of highly transmissible diseases and health threats to the community and control of environmental threats through the regulation of environmental hazards (e.g. water and

Box 1.1.1 Functions of public health

1. Prevent disease and its progression, and injuries.
2. Promote healthy lifestyles and good health habits.
3. Identify, measure, monitor, and anticipate community health needs (e.g. surveillance).
4. Investigate and diagnose health problems, including microbial and chemical hazards.
5. Formulate, promote, and enforce essential health policies.
6. Organize and ensure high-quality, cost-effective public health and healthcare services.
7. Reduce health disparities and ensure access to healthcare for all.
8. Promote and protect a healthy environment.
9. Disseminate health information and mobilize communities to take appropriate action.
10. Plan and prepare for natural and man-made disasters.
11. Reduce the impact of interpersonal violence and aggressive war.
12. Conduct research and evaluate health-promoting/disease-preventing strategies.
13. Develop new methodologies for research and evaluation.
14. Train and ensure a competent public health workforce.

Source: data from Office of the Director, National Public Health Performance Standards Program, *10 Essential Public Health Services*, Centers for Disease Control, 1994, available from www.cdc.gov/od/ocphp/nphpsp/EssentialPHServices.htm.

air quality standards and smoking). It is important to recognize that influencing politics and policies is an essential function of public health at the local, national, and global levels.

There are limited resources that can be devoted to public health and the assurance of high-quality health services. Thus, an essential function of public health is to effectively *plan, manage, coordinate, and administer cost-effective health services*, and to ensure their availability to all segments of society. In every society, there are *health inequalities* that limit the ability of some members to achieve their maximum ability to function. Although these disparities primarily affect the poor, minority, rural, and remote populations and the vulnerable, they also impact on society as a whole, particularly in regard to infectious and/or transmissible diseases. Thus, there is not only an ethical imperative to reduce health disparities, but also a pragmatic rationale.

Technological advances and increasing commerce have done much to improve quality of life, but these advances have often come at a high cost to the environment. In many cities of both the developed and developing world, the poor quality of air—contaminated by industry and commerce—has affected the respiratory health of the population, and has threatened to change the climate, with disastrous consequences locally and globally. We have only one world. If we do not take care of it, we will ultimately have difficulty living in it. Through education of the public, formulation of sound regulations, and influencing policy, public health can contribute much to the protection and monitoring of the environment to *ensure that it is conducive for the population to live healthily*.

To ensure that each individual in the population functions to his or her maximum capacity, public health needs to *educate the public, promote adoption of behaviours associated with good health outcomes, and stimulate the community* to take appropriate actions to ensure the optimal conditions for the health of the public. This is vital since many major public health problems are linked to human behaviour and lifestyles. Ultimately, public health cannot succeed without the support and active involvement of the community.

We cannot predict, and rarely can we prevent, the occurrence of natural and man-made disasters, but we can prepare for them to ensure that the resulting damage is minimized. Thus, *disaster preparedness* is an essential component of public health, whether the disaster is an epidemic such as influenza or the occurrence of typhoons and other natural disasters.

Unfortunately, in the modern world, interpersonal *violence and war* have become common. In some segments of society (particularly among adolescent and young adult minority males), violence has become the leading cause of death and productive years of life lost. Public health cannot ignore the fact that violence and wars are major factors dramatically reducing the quality of life for millions.

Many of the advances in public health have become possible through *research*. Research will continue to be essential for identifying and anticipating health problems and the optimal strategies for addressing them. Strategies that seem very logical may, in fact, not succeed for a variety of unforeseen reasons. Therefore, public health systems and programmes cannot be assumed to function cost-effectively without continuous monitoring and evaluation. Thus, it is essential that new public health strategies undergo rigorous evaluation before being scaled up, and once scaled up, are periodically reviewed to ensure their continuing effectiveness in diverse groups and populations.

Over the last century, the quality of research has been enhanced by the *development of new methodologies*, particularly in the fields of epidemiology, biostatistics, and laboratory sciences. Rapid advances in computational hardware and techniques have increased our ability to analyse massive amounts of data, and to use multiple strategies to aid in the interpretation of data. Despite this, it will be a major challenge to keep pace with the explosive growth in the volume and complexity of data being generated, driven by a range of factors from the pervasive use of the Internet, social media, and mobile phones, to the masses of data from molecular biology and sequencing studies. To glean valuable insights pertinent to public health from these huge datasets will require new approaches, strategies, and methodologies. It is essential that public health continues to use leading-edge technologies to develop more sophisticated research strategies to address public health issues.

A major problem in public health has been translating research advances into effective health practice and policy in a timely manner. A new area of research, *implementation science*, has been proposed to delineate barriers to and factors that facilitate rapid translation of scientific advances into improvements in health practice and development of more effective policies promoting health.

The quality of public health is dependent on the competence and vision of the public health *workforce*. Thus, it is an essential function of public health to *ensure the continuing availability of a well-trained, competent workforce* at all levels, including leaders with the vision essential to ensure the continued well-being of society and the implementation of innovative, effective public health measures.

Finally, a thread that runs through all these functions is the necessity for much greater international collaboration in data sharing, policy formulation and implementation, and the management of specific public health issues. With globalization, the rapid flow of information, people, goods, and services across national boundaries means that many public health concerns and issues are interconnected in complex ways. Effective solutions will therefore often depend on joint action between different countries. In addition, now more than ever, there are many opportunities for major public health attainments to be made through cooperative action at the global level, as has been demonstrated in the past by milestones such as the eradication of smallpox. The media can play an important role in educating the public and in facilitating public health interventions.

Contemporary health issues

Underlying the bulk of the public health problems of the world is the issue of poverty. More than half of the world's population lives below the internationally defined poverty line, and 22 per cent of the population in developing countries lives on less than US \$1.25 per day (World Bank 2012). Although the majority of the world's poor live in developing countries, there are many poor living in the wealthiest countries of the world—underscoring the disparity of wealth between the poor and the rich in all countries. In the United States, 39.8 million Americans were living below the official poverty level in 2008. The proportion was highest among African Americans (24.7 per cent) and Hispanic Americans (23.2 per cent). Unfortunately, the disparity between the rich and the

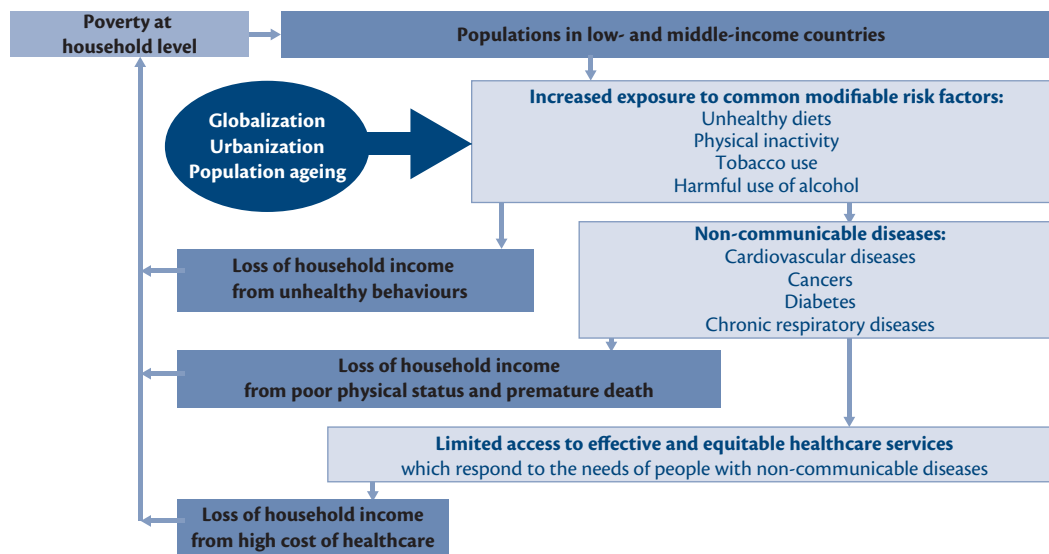

Fig. 1.1.1 From poverty to disease.

poor is increasing within countries (US Census Bureau 2009). Poverty causes a cascade of problems leading to poor health (Fig. 1.1.1). It is incumbent on public health to work to reduce the impact of these disparities to ensure that all members of the global society share in a healthy quality of life.

The twentieth century witnessed the transition of major disease burdens, defined by death, from infectious and/or communicable diseases to non-communicable diseases (NCDs). In 1900, the leading cause of death in the United States and other developed countries was reported to be pneumonia and influenza. By the beginning of the twenty-first century, diseases of the heart and other chronic diseases were the leading causes of death, and pneumonia and influenza had dropped to seventh place, primarily affecting the elderly (Tables 1.1.1 and 1.1.2). Commensurately, the average lifespan increased significantly, compounding the problems introduced by population growth. The reduction in communicable diseases was not primarily due to the development of better treatments, although vaccines played an important role in the second half of the twentieth century; public efforts to reduce crowding and improve housing, enhance nutrition, and provide clean water and safe disposal of wastes were key to reducing communicable diseases.

By 1980, many leading public health figures felt that infectious diseases had been eliminated as a primary concern for public health; however, the discovery and expanding pandemic of acquired immunodeficiency syndrome (AIDS) caused by the human immunodeficiency virus (HIV) in the early 1980s, and subsequently, the severe acute respiratory syndrome (SARS) outbreaks in the early 2000s, demonstrated the fallacy of their thinking, as do the persisting high rates of infectious diseases, particularly in Africa.

Although communicable diseases persist as a major public health concern, globally chronic NCDs have become the major health problem, accounting for 70 per cent of deaths (Table 1.1.2). Even in poor, developing countries, NCDs are a dominant and growing challenge. Nearly 80 per cent of the deaths due to

Table 1.1.1 Leading causes of death in the United States (1900, 1950, 1990, 1997, 2001, 2011)

Values expressed as rates per 100,000, age-adjusted.

Source: data from McGinnis, J.M. and Foege, W.H., Actual causes of death in the United States, *Journal of the American Medical Association*, Volume 270, Number 18, pp. 2007–12, Copyright © 1993 American Medical Association and Department of Health and Human Services, National Center for Health Statistics, *Health, United States, 1999*, US Centers for Disease Control and Prevention, Washington, DC, USA, 1999.

non-communicable or chronic diseases in 2008 occurred in developing countries, in part because many more people live in low- and middle-income countries than in high-income countries (World Health Organization 2011a). The age-standardized death rate due to NCDs among males in low- and middle-income countries was 65 per cent higher, and among females, 85 per cent higher than for men and women in high-income countries. This figure is particularly disturbing because low- and middle-income countries have

Table 1.1.2 Top ten causes of death worldwide, 2011

Causes of death	Deaths in millions	% of deaths (within income group)
Ischaemic heart disease	7.0	12.9
Stroke	6.2	11.4
Lower respiratory infections	3.2	5.9

far fewer resources and capacity to address the epidemic of NCDs. Communicable diseases, however, still accounted for 30 per cent of the burden of disease worldwide (Fig. 1.1.2), but caused a majority of deaths only in Africa. The majority of communicable diseases are now preventable through vaccines, improved sanitation, behavioural interventions, and better standards of living.

Compounding the global shift to NCDs is the rapidly rising age of populations in many countries due to increased longevity and dramatically decreased birth rates (Fig. 1.1.3) (United Nations 2002). Population growth is already below replacement in many countries, both developed and developing. This demographic shift has widespread and profound implications. It will increase the burden of chronic disease in these countries, place increasing demands on healthcare and social support services, and strain public financing systems. This will occur even as the proportion of the population in the productive ages will decrease, which in turn will impact economic growth. The low- and middle-income countries in particular will be affected by the ageing of their populations.

Measuring disease occurrence

An essential step in defining health is to identify appropriate methods for measuring it. Traditionally, public health has defined disease in terms of mortality rates because they are relatively easy to obtain and death is indisputable. The use of mortality rates, however, places the greatest emphasis on diseases that end life, and tends to ignore those which compromise function and quality of life without causing death. Thus, the problems of mental illnesses, accidents, and disabling conditions are seriously underestimated if one uses only mortality to define health.

Two other strategies to measure health that evolved in the last half of the twentieth century have been 'years of productive life lost' (YPLL) (Lopez et al. 2007) and 'disability-adjusted life years' (DALYs) (Murray and Lopez 1995). The former emphasizes those

* 'Other conditions' comprises communicable diseases, maternal and perinatal conditions, and nutritional deficiencies.

Fig. 1.1.2 NCDs constitute more than 60 per cent of deaths worldwide.

**Fig. 1.1.3** Proportion of population 60 years or older: world, 1950–2050.

Reproduced with the permission from Department of Economic And Social Affairs Population Division, *World Population Ageing: 1950–2050*, United Nations, New York, USA, Copyright © 2001, available from http://www.un.org/esa/population/publications/worldageing19502050/pdf/62executivesummary_english.pdf.

diseases that reduce the productive lifespan (currently arbitrarily defined as 75 years), whereas the latter emphasizes those diseases that compromise function but also includes a measure of premature mortality. Using either of these alternatives to define health results in very different orderings of diseases and/or health problems as public health priorities.

Using death to identify disease priorities, the leading cause is NCDs, which account for 70 per cent of diseases worldwide (Fig. 1.1.2). Among the chronic diseases, cardiovascular diseases account for half of the deaths. The proportion, however, varies markedly by regions of the world and level of affluence of the countries. Communicable diseases remain the major cause of death only in Africa, although they account for a significant proportion of deaths in South East Asia and the eastern Mediterranean. The major victims of these communicable diseases are infants and children under 5 years old. The persistence of communicable diseases in these areas represents a continuing major public health challenge.

DALYs and YPLL may be considered as better measures of the quality of life and functioning capacity of a country than mortality. Using DALYs to establish global disease priorities emphasizes communicable diseases and injuries, which tend to disproportionately affect the young, and reduces the relative importance of cardiovascular diseases and other chronic diseases that primarily affect the elderly. The WHO has projected that the ranking of total DALYs for neuropsychiatric disorders, injuries, and non-communicable and/or chronic diseases will increase by 2020, whereas the ranking for communicable diseases will decline. Communicable diseases, which currently account for 40 per cent of the DALYs, are expected to decline to 30 per cent by 2030 (Mathers and Loncar 2006).

On the other hand, according to projections by the WHO, while lower respiratory infections and diarrhoea remain the dominant communicable diseases, infections such as HIV, tuberculosis, and malaria will rise in terms of YPLL per 1000 population by 2030, even as other communicable diseases will yield to intervention efforts and account for progressively fewer YPLL (World Health Organization n.d.). The YPLL per 1000 population due to NCDs that tend to affect older people, however, is projected to remain constant, perhaps reflecting the optimism regarding the development of strategies for earlier diagnosis, better health habits, and better drugs to sustain life in patients with these conditions.

Communicable diseases

Many new vaccines against infectious agents have been and are being developed and many have become more affordable. The

WHO's regional offices working with individual countries have conducted intensive immunization programmes against the major preventable infectious diseases of childhood, but there are significant barriers to complete coverage, including poverty, geographic obstacles, low levels of education affecting willingness to accept vaccination, logistical problems, civil unrest and wars, corruption, and mistrust of governments. Poverty, weak governments, and misuse of funds have also prevented the control of disease vectors that play a key role in diseases such as malaria and dengue, provision of clean water, and safe disposal of sanitation, all essential for the control of communicable diseases. (See Table 8.11.1 in Chapter 8.11.)

Another major factor in the rapid spread of communicable diseases has been the rapid growth in transportation. It is now possible for an individual with a communicable disease to circumnavigate the globe while still infectious and asymptomatic. Thus, cases of SARS were reported throughout South East Asia and as far as Canada within weeks of the recognition of the first cases in Hong Kong (Lee 2003). Similarly, due to the extensive global food supply chains, food-borne infections can spread rapidly within and across countries.

Another source of communicable diseases is the continuing emergence of new infectious agents, many of them adapting to humans from animal sources. Fig. 1.1.4 identifies new disease outbreaks from 1981 to 2003, including newly drug-resistant variants of new diseases occurring worldwide. Changes in food production, crowding of animals, mixing of live animal species in 'wet markets' (selling live animals for food) in Asia and elsewhere, and the introduction of hormones and antibiotics into animal feed have all contributed to the emergence of these new diseases.

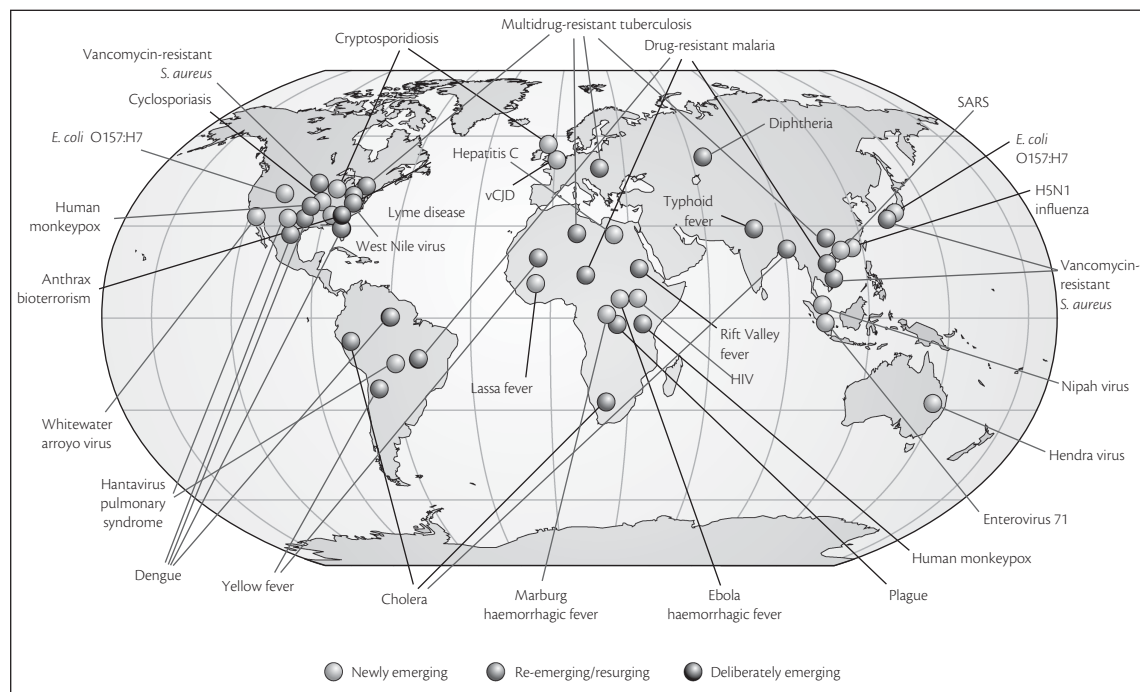

Fig. 1.1.4 Emerging and re-emerging disease worldwide, 1981–2003.

Table 1.1.3 lists many of the new diseases that have been recognized since 1980, and Box 1.1.2 lists the factors that contribute to the emergence of these new agents and disease threats.

In addition to the diseases listed in Table 1.1.3, antibiotic-resistant strains of known agents have emerged rapidly due, in part, to the widespread inappropriate use of antibiotics. Thus, resistant strains of gonorrhoea, *Staphylococcus*, tuberculosis, and malaria have become major problems. The latter two have now emerged as two of the three current major infectious disease problems globally. The development of drug-resistant malaria has been compounded by the emergence of vectors resistant to the commonly used chemical insecticides. The frightening potential for rapid and dangerous spread of antibiotic resistance through genetic elements that are transmissible between different bacterial species, was highlighted by reports of the speed and extent by which New Delhi metallo-beta-lactamase (NDM-1) which encodes multiple-antibiotic resistance, spread to many different countries (Moellering 2010).

Approximately 1 billion people, one-sixth of the world's population, suffer from one or more tropical disease, including Buruli ulcer, Chagas' disease, cholera, dengue, dracunculiasis, trypanosomiasis, leishmaniasis, leprosy, lymphatic filariasis, onchocerciasis, schistosomiasis, helminthiasis, and trachoma (WHO 2006). The functional ability of those so afflicted is severely compromised, in turn affecting the economic competitiveness of the poorest countries, which suffer the greatest burden of these tropical diseases. However, major strides have been achieved in reducing the burden of diseases such as leprosy, guinea worm disease, and lymphatic filariasis. Continuing efforts are needed to further reduce the burden of these and other tropical diseases.

Box 1.1.2 Factors contributing to the emergence or re-emergence of infectious diseases

1. Human 'demographic change' by which persons begin to live in previously uninhabited remote areas of the world and are exposed to new environmental sources of infectious agents, insects, and animals.
2. People living in close proximity to domestic animals, poor animal husbandry in many parts of the developing world leading to zoonotic infections.
3. Breakdowns of sanitary and other public health measures in overcrowded cities and in situations of civil unrest and war.
4. Economic development and changes in the use of land, including deforestation, reforestation, and urbanization.
5. Climate changes cause changes in geography of agents and vectors.
6. Changing human behaviours, such as increased use of child-care facilities, sexual and drug-use behaviours, and patterns of outdoor recreation.
7. Social inequality.
8. International travel and commerce that quickly transport people and goods vast distances.
9. Changes in food processing and handling, including foods prepared from many different animals and transported great distances.
10. Evolution of pathogenic infectious agents by which they may infect new hosts, produce toxins, or adapt by responding to changes in the host immunity (e.g. influenza, HIV).
11. Development of resistance of infectious agents such as *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae* to chemoprophylactic or chemotherapeutic medicines.
12. Resistance of the vectors of vector-borne infectious diseases to pesticides.
13. Immunosuppression of persons due to medical treatments or new diseases that result in infectious diseases caused by agents not usually pathogenic in healthy hosts (e.g. leukaemia patients).
14. Deterioration in surveillance systems for infectious diseases, including laboratory support, to detect new or emerging disease problems at an early stage.
15. Illiteracy limits knowledge of prevention strategies.
16. Lack of political will—corruption, other priorities.
17. Biowarfare/bioterrorism—an unfortunate potential source of new or emerging disease threats (e.g. anthrax and letters).
18. War, civil unrest—creates refugees, food and housing shortages, increased density of living, etc.
19. Famine.

We now recognize that we will continue to see new human pathogens emerging in the future, and need to be prepared to contain them. Unless the world realizes the consequences of not protecting

the environment in which we live, and acts on it, newly emerging diseases will continue to plague us.

Non-communicable diseases

With increasing control of communicable diseases and increasing lifespan, NCDs have emerged as the major global health problem in both developed and developing countries. Even in developing countries, NCDs have assumed greater importance. The prevalence of type 2 diabetes in rural India is 13.2 per cent (Chow and Raju 2006). Cardiovascular diseases have become a major cause of death in China. During 2000–2008, the incidence of stroke in low- and middle-income countries exceeded that in high-income countries by 20 per cent (Feigin et al. 2009).

The causes of NCDs are many and complex. Although the immediate causes are factors such as raised blood pressure, increased blood glucose, abnormal lipids and fat deposition, and diabetes, the underlying causes are behavioural and social. These behavioural factors include unhealthy diets that substitute pre-packaged and fast foods high in fats for a balanced diet, physical inactivity, and, especially, tobacco use; these in turn are the products of social change, including globalization, urbanization, and aging. WHO estimated that insufficient physical activity contributed to 3.2 million deaths and 32.1 million DALYs in 2008, and that obesity contributed to 2.1 million deaths and 35.8 DALYs globally (WHO 2011a). Some NCDs have been associated with infectious disease agents. For example, *Chlamydia pneumoniae* has been implicated in the development of atherosclerosis (Kuo and Campbell 2000), hepatitis C is a leading cause of hepatocellular (liver) cancer, and human papilloma virus (HPV), is a cause of cervical cancer. Recently, an effective vaccine has been developed, which protects against cervical cancer, but it is expensive and must be administered before sexual activity begins (i.e. early adolescence).

Fig. 1.1.5 shows the global distribution by gender of deaths from NCDs, demonstrating the higher rates of death from NCDs in developing countries, especially in Africa.

Another aspect of NCDs is the increasing survival of affected individuals who would not have survived as long previously. However, many of them are left with disabilities that require modified environments to experience a reasonable quality of life and to realize their full potential in order to contribute to society. Most NCDs can be reduced by a combination of healthy behaviours, including not smoking, moderate alcohol use, and exercise (Breslow and Breslow 1993). Many developed countries have been promoting healthy lifestyles, but there is a need for greater emphasis and development of these programmes in developing countries, where the major global burden of chronic diseases occurs.

Mental illness

Public health professionals have only relatively recently recognized the importance of addressing the mental health needs of society on a global scale, partly due to the difficulties in defining it. It is now estimated that 10 per cent of the world's population suffers from mental illness at any given time, and that mental illness accounts for 13 per cent of the global burden of disease (Collins et al. 2011) (Table 1.1.4). Mortality rates seriously underestimate the burden of mental health on society. The true extent of mental illness is probably greater—only 60 per cent of countries

report having a dedicated mental health policy and only 27 per cent report data on expenditures for mental health (WHO 2011b).

Global provisions for treatment of mental illness are still significantly below what is necessary to adequately address the problem. In developing countries, only US \$0.25 is allocated per patient for mental health and there is less than one psychiatrist per 200,000 persons (WHO 2011b). Of those with mental illness in developing countries, 76–85 per cent do not have access to appropriate care (WHO 2011b). Although 87 per cent of the world's governments offer some mental health services at the primary care level, 30 per cent of them have no relevant programme, and 28 per cent have no budget specifically identified for mental health. Mental illness robs society of a significant number of potentially productive persons. With the diminishing proportion of productive people of working age and the increasing proportion of elderly dependants, it is important to assist those who are not productive because of mental illness to become healthy, productive members of society.

Population projections

Although the rate of growth of the world's population has slowed in the latter half of the twentieth century, the world's population, currently over 7 billion people, is still estimated to grow to 9 billion by 2050. The growth in the population will be mostly among the elderly and the old elderly (those over 80 years of age).

The well-being of society is dependent on the ratio of those who produce to those who are dependent. Improved technology and strategies will be required to increase worker productivity, because the majority of the population growth in the coming decades will be among the old and old elderly, not through increasing birth rates, and will result in a diminishing proportion of producers and an increasing proportion of dependants. It is also expected that more of the elderly will have to continue to be economically productive. In 2000, the proportion of the world's population who were 65 years and over was 8 per cent; by 2050, it will be at least 30 per cent (Index Mundi 2012). This will be further exacerbated because the majority of the oldest elderly will be single women who traditionally have more limited resources and lower levels of education, particularly in developing countries. The productivity and efficiency of those who produce must increase if we are to sustain and improve the quality of life for all.

The occurrence of disease in old age is directly correlated with unhealthy behaviours developed in early life. Unfortunately, concurrent with population growth, there has been a worldwide epidemic of obesity and decreased physical activity, which has increased the proportion of elderly who suffer from chronic debilitating diseases in both the developed and developing world. Thus, unless efforts to promote healthy lifestyles are successful, not only will there be an increase in the proportion of elderly, but also an increasing proportion of them will require assistive care, placing a further economic and social burden on families and society.

As the population grows, there is increasing pressure to provide food, water, and other necessities to maintain a high quality of life. Shifts in dietary preferences in developing countries towards greater meat consumption also puts additional strains on food production. Fertile farmlands are increasingly being converted to residential, commercial, or industrial use. Thus, more people will effectively need to be supported on less arable land. Food security will hence be a key issue for the future and this will be affected by a multitude of factors but most notably sufficiency of water

resources and whether there will be major increases in agricultural productivity.

Other public health issues

Nutrition

Appropriate nutrition is essential for health. In many developing countries (as well as among the poor and homeless in developed

countries), undernutrition is a problem. Beyond access to nutritious and safe food, many of the poor have little knowledge about what constitutes a healthy diet, compounding the difficulties. At the same time, in developed and many rapidly developing countries such as China, overnutrition and obesity are a major problem. Some industry sectors have been more effective in promoting calorie-dense, salt-rich, and unhealthy diets than public health

Table 1.1.4 Global burden of mental, neurological, and substance-use (MNS) disorders

Rank	Worldwide		High-income countries [†]		Low- and middle-income countries	
	Cause	DALYs [‡] (millions)	Cause	DALYs (millions)	Cause	DALYs (millions)
1	Unipolar depressive disorders	65.5	Unipolar depressive disorders	10.0	Unipolar depressive disorders	55.5
2	Alcohol-use disorders	23.7	Alzheimer's and other dementias	4.4	Alcohol-use disorders	19.5
3	Schizophrenia	16.8	Alcohol-use disorders	4.2	Schizophrenia	15.2
4	Bipolar affective disorder	14.4	Drug-use disorders	1.9	Bipolar affective disorder	12.9
5	Alzheimer's and other dementias	11.2	Schizophrenia	1.6	Epilepsy	7.3
6	Drug-use disorders	8.4	Bipolar affective disorder	1.5	Alzheimer's and other dementias	6.8
7	Epilepsy	7.9	Migraine	1.4	Drug-use disorders	6.5
8	Migraine	7.8	Panic disorder	0.8	Migraine	6.3
9	Panic disorder	7.0	Insomnia (primary)	0.8	Panic disorder	6.2
10	Obsessive–compulsive disorder	5.1	Parkinson's disease	0.7	Obsessive–compulsive disorder	4.5
11	Insomnia (primary)	3.6	Obsessive–compulsive disorder	0.6	Post-traumatic stress disorder	3.0
12	Post-traumatic stress disorder	3.5	Epilepsy	0.5	Insomnia (primary)	2.9
13	Parkinson's disease	1.7	Post-traumatic stress disorder	0.5	Multiple sclerosis	1.2
14	Multiple sclerosis	1.5	Multiple sclerosis	0.3	Parkinson's disease	1.0

[†]World Bank criteria for income (2009 gross national income (GNI) per capita): low income is US \$995 equivalent or less; middle income is \$996–12,195; high income is \$12,196 or more.

professionals have been in championing healthy food choices consumed in reasonable quantities. This has particularly been the case for the youth, and has contributed to rising childhood obesity in many countries, including the more affluent in developing countries.

Oral health

Good dental health is essential for maintaining adequate nutrition and a good quality of life. Worldwide, however, 60–90 per cent of school children and nearly 100 per cent of adults have dental cavities. About 30 per cent of adults aged 65–74 years have no natural teeth. It was also estimated in 2004, that globally, there was an average of 1.6 decayed, missing, or filled teeth (DMFT) among children aged 12 years old (WHO 2004). These high rates of dental problems reflect poor dental hygiene and preventive care (Pine and Harris 2007). Unfortunately, many people believe that dental care is an expendable luxury, and that visits to dentists are only necessary when there is a problem. Oral cancers are the sixth most common cause of cancer globally, with the 5-year prevalence estimated to be 6.8 per cent globally (WHO 2004). Poor dental hygiene is an important risk factor, together with smoking as well as the habit of betel nut chewing which is common in parts of Asia. Clearly the public health message regarding the importance of good dental hygiene, regular tooth-brushing, and regular dental check-ups is not reaching the majority of the people.

Injuries

Injuries and violence caused 5.8 million deaths in 2011, of which 1.6 million were due to global violence, 1.3 million to traffic accidents, and 844,000 to suicide. Deaths due to injuries are almost three times greater in developing than in developed countries. However, most of the injuries do not cause death, but may result in disability. Furthermore, they occur more commonly among younger persons and children. Injuries can be broadly categorized into the following groups: motor vehicle accidents, suicide, homicide, and unintentional injuries, including occupational injuries and falls. Motor vehicle accidents account for the largest proportion of deaths due to injury. The WHO projects that motor vehicle accidents will become the third highest cause of DALYs globally by 2020 (WHO 2013). Falls, particularly among the elderly, are a major cause of DALYs as well.

Unintentional injuries are largely preventable through community and governmental intervention. Thus, improved roads, separation of different modes of transportation, enactment and enforcement of seat belt and helmet laws, and improved designs of automobiles, ladders, and other equipment and tools have all been shown to significantly reduce injuries and deaths due to accidents.

Homicide, violence, and suicide

Homicide, violence, and suicide represent a growing problem, particularly among the young. Homicide and suicide are among

the leading causes of death globally. In some minority groups in the United States, homicide and violence are the leading cause of death of youth, followed by suicide. In China, suicide remains the leading cause of death among women in rural areas. Globally, the WHO predicts that homicide and suicide will account for an increasing proportion of deaths. The WHO predicts that by 2020, war will become the eighth highest cause of DALYs, violence (including gender-based and personal) the twelfth, and self-inflicted injuries the fourteenth (Murray and Lopez 1997).

Vulnerable populations

Public health has always been concerned with the health and well-being of vulnerable groups who require special attention. The definition of a vulnerable population varies by time, situation, and culture, but the common characteristic across all vulnerable groups is their special susceptibility to adverse health and poor quality of life. The list of vulnerable groups includes the poor, minorities, women, children, the elderly, the handicapped, the illiterate, orphans and street children, immigrants, rural-to-urban migrants, refugees and displaced people, the homeless, and the mentally ill. In certain situations, other groups may be considered vulnerable. For example, in the face of epidemics such as HIV/AIDS, one should also consider adolescents to be a vulnerable group. Often vulnerable individuals live at the margins of society and have difficulty accomplishing the basic functions of living and accessing healthcare. Thus, they require assistance. In many societies, particularly in developing countries, the family acts as the safety net for these groups, but if the family itself is vulnerable or dysfunctional, this safety net is absent. Societies with ample resources have developed social support programmes that assist the vulnerable, but these programmes seldom cover the full range of vulnerable groups, and may not adequately support those whom they target. Universal access to healthcare is one component of assisting the vulnerable, but presently, even in rich, developed countries such as the United States, healthcare is not available to all, and strategies to fund universal healthcare are difficult to implement.

In almost every country, developed and developing, there are homeless people, many of whom suffer from multiple problems, including mental illness. The ability to function adequately and achieve good health among many vulnerable groups, including the homeless, mentally ill, alcoholics, and drug addicts, is adversely impacted by additional factors such as poverty, prejudice, and stigmatization by society. Thus, programmes to assist the vulnerable need to also encourage society to take supportive action, in order to be optimally effective. This is a particular challenge in respect to persons with handicaps. Many developed countries have adequate provision for persons with handicaps, but in poorer countries, those with handicaps face substantial difficulties to function in society, and many do not survive.

In designing programmes for vulnerable groups, a further complication is the fact that the specific problems and needs of each of these groups differ, and they thus require public health actions which are more tailored to their requirements. For some of these groups, such as mothers and children and the handicapped, there are well-established programmes, although coverage is far from complete and the quality of these programmes varies widely. For others, such as the illiterate and migrants, there are fewer established programmes. If we are to meet the public health goal of 'Health for

All', we need to identify and assist the vulnerable groups within societies to achieve their maximum possible health and function.

The environment

Environmental health comprises those aspects of human health, including quality of life, that are determined by physical, chemical, biological, social, and psychosocial processes in the environment.

Draft definition developed at a WHO consultation in Sofia, Bulgaria, 1993 (WHO Regional Office for Europe 1994)

Currently, one of the major problems which the world faces is the deterioration of the environment caused by the increasing numbers of people and the accumulation of wastes produced by them, their vehicles, and the industries they support. Thus, the quality of the air that we breathe has declined, especially in developing countries where rapid economic growth has been achieved at the expense of the environment. The most polluted cities of the world are concentrated in developing countries, which often have the least capacity and political will to reduce pollutants. Pollution of the world's oceans, which receive massive amounts of biological and chemical wastes annually, affects not only the quality of the water but also the ability of the ocean to sustain marine life, an important source of food.

The number of known chemicals globally exceeds 14 million, of which over 60,000 are commonly used. All of these ultimately end up in the environment. They are the result of the huge proliferation of industry, technology, and automobiles in the twentieth century. The full health effects of many of these chemicals are still unclear and difficult to establish. Murray and Lopez (1995) estimated that 1,379,238 DALYs are caused annually by environmental pollutant exposures. As the twenty-first century progresses, the number of pollutants will continue to increase.

Problems of the environment occur at the personal level (at home and the workplace), the community level (e.g. air and water pollution), and globally (e.g. global warming, hazardous and radioactive waste). Although these problems may be viewed separately, they are in fact all global issues affecting both local and remote populations. Thus, slash-and-burn agricultural practices in Indonesia result in periodic, and sometimes severe, air pollution problems in neighbouring Singapore and Malaysia. Industrial pollutants released in the industrial states of northeastern United States cause acid rain, which adversely affects crops and people in the midwestern United States and southern Canada. Pollution of rivers upstream can adversely affect communities and countries downstream, as happened, for example, in 2005 when nitrobenzene was released into the Songhua River in Heilongjiang, China, contaminating drinking water downriver in both China and Siberia, Russia.

Air pollution

The rapid increase in automobiles and industry has caused widespread air pollution in most urban areas of the world, the worst occurring in the developing countries, which have rapidly industrialized at the expense of their environment. Now, in the early part of the twenty-first century, many of these countries are realizing the need to protect the environment. Unfortunately, reversal of decades of pollution is far more difficult and costly than prevention.

The harmful effects of air pollution extend beyond the environment. Many members of society, including asthmatics and persons with chronic respiratory disease, are vulnerable to even relatively low levels of pollutants. Studies of the urban air in Southern California have demonstrated that children chronically exposed to high levels of both primary pollutants and photochemical oxidants have decreased lung function (Detels et al. 1979). Studies have demonstrated that children living near freeways in Southern California also suffer long-term lung damage (Gauderman et al. 2007). Levels of pollutants observed in many developing countries, especially in China and India, are considerably higher than in developed countries. Studies have documented the serious health effects of long-term exposure to the levels of pollutants occurring in China (Chen et al. 2004; Wong et al. 2008). However, the true cost of uncontrolled industrialization and pollution in these countries is not known.

Indoor pollution is a particular problem in developing countries where cooking is traditionally carried out using coal or charcoal fires in poorly ventilated houses. However, it is also a problem in wealthier countries in which harmful chemicals are used for cleaning and household construction.

Water pollution

Those who live in developed countries take the provision of safe drinking water for granted, but 40 per cent of the world's population does not have access to clean drinking water, a basic necessity of life. As the world population expands, the production of waste increases, and the problem of protecting water supplies also rises. Approximately 60 per cent of the world does not have adequate facilities for waste disposal. Even in leading cities in developed countries, pollution of the water supply can occur, as happened in Milwaukee, Wisconsin, when cryptosporidia contaminated the water supply, causing severe illness and death, especially in vulnerable populations compromised by immune deficiency disorders (MacKenzie et al. 1994). The increased rate of upper respiratory infections and gastrointestinal disorders among surfers and others using the ocean for recreational purposes has been well documented. Beaches in most urban areas are frequently closed when the sewage disposal systems that drain into the vicinity become overwhelmed. Acid rain from industrialization has caused acidification of lakes, making them inhospitable for fish and other marine life, thus compromising the food supply. Recently there has been discussion about whether the benefits of omega-3 fatty acids found in fish outweigh the risk of mercury poisoning among those who eat large quantities of fish. Ensuring a safe, adequate water supply for people in both developed and developing countries must become a public health priority.

Other pollutants

As the population of the world rapidly increases and technology produces new substances and processes, not only the amount of pollutants, but also the varieties of pollutants increase. As new substances are developed, it would be ideal if their use is not permitted until plans and provisions have been developed and implemented for their safe disposal. However, this is often not the case in practice.

Biodegradable pollutants have a limited lifespan in the environment, but we are increasingly producing non-biodegradable substances such as plastics, which are now ubiquitous, and hazardous

materials such as radioactive wastes that persist for generations. The problem of discarding these materials safely has become a major public health issue. In some cases, developed countries are paying developing countries to accept their hazardous waste products. This strategy does not solve the problem, but shifts it to those countries that have fewer resources with which to deal with the challenge.

In the last decade, nanoparticles (1 nanometre is 1 billionth of a metre) have been increasingly used in the production of foods, drugs, cosmetics, and other products used by humans. Particles of this small size become reactive in the body and, according to recent reports (Li et al. 2009), can cause serious damage to lung cells, the liver, and brain cells. Given this problem, it is important that the use of nanoparticles in products intended for human use be regulated.

Climate change

One of the most serious, long-term challenges of the twenty-first century is global warming due to the release of carbon dioxide and other 'greenhouse gases'. There is growing evidence that the consequential climate change will be associated with increased public health risks (Patz et al. 2005).

A major review by WHO to assess the public health impact of anthropogenic climate change to date, estimated that from the mid 1970s, climate change might already have contributed to 150,000 deaths and about 5 million DALYs per year. These are largely related to increased incidence of conditions such as malnutrition, diarrhoea, and malaria (WHO 2014). Mitigating the health impact of global warming and climate change at the regional level, will be a major public health issue for this century.

Rescuing the environment

To prevent further degradation of the environment and to tackle the threat of global climate change, strong political will is required of the countries of the world. For example, while the United States is one of the world's major producers of carbon dioxide and other greenhouse gases, it has yet to ratify the United Nations Framework Convention on Climate Change, an international treaty aimed at stabilizing global greenhouse gas at levels that would avoid dangerous climate change.

From a public health perspective, it is unrealistic to expect that the risks from environmental pollution and hazardous waste can be reduced to zero. Instead, the concept of 'acceptable risk' will continue to be a part of the process. Determining the level of acceptable risk will probably be arrived at through an interplay of the scientific data and evidence, with policy and political judgments. Public health professionals and researchers must endeavour to play a strong role in these determinations.

Occupational health

Occupational diseases are different from other diseases, not biologically, but socially.

Henry Sigerist, 1958 (Sigerist 1958–1961)

The International Labor Organization's Health and Safety Programme estimated that there were 2.3 million work-related deaths, 340 million work-related injuries, and more than 160 million cases of occupational disease annually worldwide (International Labor Organization 2011). In some developing countries, child labour is still the norm. Twelve million serious injuries occurred among young workers. This affects more people

than those who have myocardial infarcts (heart attacks), strokes, or newly diagnosed malignancies annually. A significant proportion of these deaths and injuries are preventable by improving safety in the workplace. However, safeguarding the health of the worker often receives less priority than the need to produce goods cheaply, especially in developing countries.

The nature of the workplace is constantly changing, with increasing proportions of workers being involved in services industries rather than in manufacturing. Over the last decade particularly, the production of goods has shifted rapidly to developing countries, where labour costs are lower. The manufacturing industry in these countries is often subject to fewer and less comprehensive safety regulations, and in some cases, are associated with low salaries and few or low healthcare benefit provisions for workers, especially for migrant workers from rural areas. Increasingly, women are entering the workforce and must juggle work and family. Larger numbers of workers are being employed on an informal part-time basis. While this reduces labour costs for industry, these informal part-time workers do not usually receive work-related benefits. They now represent 50 per cent or more of the workforce globally. This segment of the workforce is particularly vulnerable to injury and limited access to healthcare.

As noted earlier, the population is ageing, and the proportion of the population that are economically active is diminishing. In response to this change, the age of eligibility for social security benefits in the United States is increasing, and mandatory retirement is being phased out. It is now projected that the proportion of workers over the age of 60 will increase to 20 per cent in Japan and 10 per cent in the United States by 2030 (Population Projections 2000). The needs of older workers are different from those of younger workers. Thus, the changing nature of the workforce will require corresponding changes in work safety regulations and health benefits to ensure a healthy, productive workforce.

Provision of and access to healthcare

Access to preventive and curative care is a requirement for health in every society, whether rich or poor. Access to affordable healthcare has long been a problem for the poor and for rural residents, especially in developing countries. However, in the United States, access to healthcare is even a problem for the middle class. Health insurance is prohibitively expensive and beyond the reach of many in the middle classes, unless it is subsidized by employers. Increasingly, employers are attempting to free themselves from the cost of health insurance for their employees through a variety of strategies. The elderly also have problems with healthcare; because healthcare costs increase with age, insurance companies are less willing to cover the elderly, and many governments, even in developed countries, do not provide adequate support for the elderly. Recently, President Obama and the US Congress implemented the Affordable Care Act, which will extend coverage significantly, but it is vigorously opposed by the Republican political party. In developing countries, the rural poor are particularly at risk. Few health professionals are willing to work in rural areas, and the cost of providing care in less populated areas is greater than in urban areas. Innovative strategies are needed to promote universal coverage and ensure that the rural poor and elderly have access to reasonable healthcare.

Bioterrorism and war

The history of use of biological weapons in war extends back for hundreds of years. In the Middle Ages, corpses of plague victims were catapulted into castles under siege. Recently, anthrax was used to contaminate the US postal system, resulting in several deaths. There has been a sharp increase in bioterrorist activities in this century. The WHO and public health agencies of individual countries have developed plans to quickly diagnose and control bioterrorist incidents. However, these threats to the health of the public will continue until we address the underlying causes of terrorism and bioterrorism.

Few actions can have the magnitude of negative impact on the health of the public that war has. Men, women, and children are killed, children are forced to serve as soldiers, homes are destroyed, major segments of the population become displaced refugees, and the social and/or economic fabric of the countries involved is destroyed. Recovery usually takes years to decades. The outside world, particularly those countries adjacent to warring nations, must cope with the huge influx of displaced persons, and action needs to be implemented to help those still in the country suffering from the impact of the war. The consequences of war are so severe and wide-ranging that it is imperative that better ways be reached to resolve international conflicts. The resources ploughed into armed conflict could be better deployed on humanitarian and public health support.

Ethics in public health

Although ethical issues are implicit in the delivery of public health, it was only after the Second World War and the recognition that 'scientific experiments' in Nazi Germany violated human rights that an emphasis was placed on recognizing the ethics of public health actions, particularly research. The Declaration of Helsinki (World Medical Association 2002), the Belmont Report (US National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1979), and the Council for International Organizations of Medical Science (2002) have promulgated ethical guidelines for research and the establishment of institutional review boards worldwide to ensure that medical and/or public health research is conducted ethically and does not violate human rights. However, there are inherent ethical conflicts in many public health actions. For example, some consider that the human rights of 'typhoid Mary', a typhoid carrier who insisted on working as a cook in the early twentieth century, were violated when she was incarcerated to prevent her from continuing to prepare food that initiated epidemics. Protecting the human rights of a man to refuse testing for HIV may result in his unknowingly infecting his wife, yet-to-be-born children, and other sexual contacts. By protecting his human rights, the human rights of his wife or partner and future family will be violated.

Implementing public health programmes and research often results in ethical conflicts and the need to balance the good of society against potential harm to the individual. It is usually necessary to inform society, particularly those who will be involved in the public programme or research, about the nature of the ethical conflicts inherent in action. For example, a trial evaluating the effectiveness of prophylactic treatment to prevent HIV infection in sex workers in Cambodia was stopped by the prime minister, who felt that the prevention trial exploited Cambodian

sex workers. A more intense effort on the part of the researchers to inform the public and politicians about the nature of the study and the potential benefit to sex workers, not only in Cambodia, but globally, might have averted this unfortunate outcome.

Public health interventions

One important task of public health professionals is to raise the level of anxiety of the public about public health problems to the level at which they will be willing to take an appropriate action. In this, an appropriate balance has to be struck since raising the level of anxiety too little will result in inadequate or no action, while raising the level too high may promote a fatalistic attitude and, as in the case of the recent HIV/AIDS epidemic, may promote stigmatization and isolation of affected individuals, seriously complicating the task of intervention. The difficulty for the public health professional is creating the level of anxiety that results in the required action while minimizing unintended consequences.

Public health interventions can be divided into four categories: social/biological/environmental, behavioural, political, and structural. The public health professional must use strategies in all four categories to achieve the maximum health of the public.

Social, biological, and/or environmental interventions

The strategy that has had the greatest impact on improving the health of the public has been an improved standard of living, including provision of clean water and safe disposal of wastes. Unfortunately, these interventions have not reached much of the world where crowding, unsafe and insufficient water, and accumulation of wastes, inadequate housing, and a lack of economic development persist.

The most cost-effective biological intervention strategy is immunization, in part because it requires minimal behavioural change and usually only a single series of actions. The WHO has taken the lead in promoting vaccine coverage worldwide through its Expanded Programme on Immunization. The appropriate use of vaccines has virtually eliminated the majority of childhood infections from the developed countries and significantly reduced them in most developing countries. Smallpox, a major infectious disease problem until the latter half of the twentieth century, has now been eliminated. We are well on our way to eliminating polio, but more challenges, such as hepatitis, tuberculosis, and measles, remain. However, it is important to realize that development and production of a vaccine is only the first step. An effective vaccine against smallpox was available for over 150 years before smallpox was eliminated. The key was the strategy of vaccine coverage, 'search and contain', together with adequate political will and funding that permitted global elimination of that disease. Thus, the strategy for utilizing the vaccine is perhaps equally important as the efficacy of the vaccine itself.

Another biological strategy is to eliminate the vectors of disease, the major approach currently in use for the control of dengue, arboviral diseases, and many of the parasitic diseases. However, overzealous use of pesticides can also create problems. For example, dichloro-diphenyl-trichloroethane (DDT), used widely in the twentieth century as an insecticide, still contaminates the

food supply, creating other health problems, including the risk of malignancy.

Treatment can also be considered a biological intervention strategy. To confront tuberculosis, one of the major infectious diseases of the twenty-first century, directly observed treatment short course (DOTS) has been successfully implemented in countries where the disease persists, and reduces transmission and development of multidrug-resistant TB. Treatment of sexually transmitted infections and contacts is a major strategy for control of transmission, but has yet to prove effective in stopping the current epidemic. Recently there has been optimism that treatment as prevention can result in control of HIV (Cohen 2011).

Behavioural interventions

Most public health interventions depend ultimately on behaviour, whether it is personal or community behaviour. At the personal or individual level, promotion of good health habits and avoidance of smoking, excessive alcohol use, and other dependency disorders are important interventions that have a major impact on health. At the community level, attitudes towards acceptable sexual behaviour and persons with dependency disorders and stigmatizing diseases are key to establishing community 'norms' that promote a healthy lifestyle and include all segments of society. However, modifying individual behaviour and community norms is difficult; it is even more difficult to ensure persistence of the modified behaviour. Yet, the majority of the public health interventions will not be successful unless they are embraced and sustained by the community at the local, national, and international levels, and accompanied by appropriate regulations and policies. The success of the antismoking campaigns in the United States and Britain and population control in China (the one-child policy) affirm that it is possible to change community norms.

Many theories identifying strategies to modify behaviour have been proposed. One of the most interesting is the Popular Opinion Leader model (Kelly 2004), which utilizes the natural leaders found in any social group as agents of change. In the United States, this strategy has been demonstrated to change behaviour in groups of men who have sex with men, and is now being evaluated in other populations worldwide. Ultimately, if public health interventions are to be effective, they must be adopted by the community. The media can play an important role in facilitating these interventions and assuring that they become community norms.

Political interventions

Public health *is* politics. Any process that involves obtaining the support of the public will involve politics and differing points of view. For example, the campaign to stop smoking was strongly opposed by the tobacco industry, which spent millions of dollars trying to counter the many reports on the adverse health effects of smoking. Countering the efforts of the tobacco industry required obtaining the political support of the public in order to pass laws and regulations limiting smoking, placing health warnings on cigarette packages, and raising taxes on cigarettes. Many needed regulations transcend boundaries and require international cooperation (e.g. regulation of greenhouse gases).

If we are to succeed in safeguarding the oceans, inland waters, and the air we breathe, it will be through the political process requiring global coordination and joint action. This process has already begun in many of the developed countries, which have

passed strong laws regulating the emissions from automobiles and factories. Now this process must be expanded to the developing countries, where the worst pollution is currently occurring.

One of the most urgent issues before the public today is the battle over emission of 'greenhouse gases', which are causing a rise in temperatures globally. This temperature rise will adversely affect the quality of life of our children, grandchildren, and their grandchildren. Unfortunately, we have not yet achieved the collective political will to take the necessary steps to arrest or reverse this detrimental warming trend.

It is important that the political process to put in place measures to improve the health of the public be based on sound scientific evidence. Pushing agendas not based on sound scientific evidence will undermine the credibility of public health professionals and our ability to accomplish our legitimate goals. Obtaining this evidence is not always easy. For example, accumulating evidence on the long-term (induction period of years to decades) impact of adverse exposures is not easily established, and often requires extrapolation from data on the impact of acute high-dose exposures to lower doses. This often requires relying on models, which are difficult for the public to understand, and are often subject to debate, even within the scientific community.

Structural interventions

An important end-point of the political process is the passage of laws and regulations. This action, if implemented, can have a very significant impact on the improvement of the health of the public. For example, the law reducing the maximum speed in California from 65 to 55 miles per hour had a significant impact on lowering the automobile fatality rate; unfortunately, this lower speed limit has been reversed. The passage and enforcement of helmet laws for motorcycles in Indonesia reduced the incidence of associated brain injuries and deaths. The incidence of lung cancer and heart disease among men has been significantly reduced, partly due to the laws regulating smoking in public spaces and the high taxes imposed on cigarettes. Many of the current public health problems of the world, particularly those involving protection of the environment, can be addressed best through structural changes requiring passage and implementation of laws and regulations. To accomplish this will require changing the attitudes and behaviour of the public and ensuring that public health regulations and laws are enforced.

Private support of public health

Private support has played an important role in the development of public health, especially in the twentieth century. The Rockefeller Foundation supported the first school of public health in the United States at Johns Hopkins University; set up the International Health Commission in 1913; established the China Medical Board in 1914, which established the first public health university in China, the Peking Union Medical College, in 1921; and has continued to contribute to global health since its founding in 1913 (Brown 1979; Berman 1983). Other foundations, including the Gates Foundation, the Ford Foundation, the Carnegie Foundation, and the Robert Wood Johnson Foundation, have made similar significant contributions to public health.

Private support of public health has been implemented through three strategies: establishment of charitable foundations by

industry; development of international, national, and local non-governmental organizations (NGOs); and direct contributions by industry. Each makes and can continue to make a significant contribution to the health of the public.

Foundations have contributed enormously to the advancement of public health, but most identify their own priorities for funding. Usually they provide support for important public health needs, but foundations and public health leaders do not always agree on what the most important priorities are. Massive infusions of money into public health by organizations such as the Gates Foundation, which makes contributions to fight HIV, malaria, and tuberculosis, can have a significant positive impact, but they also tend to influence public health priorities. Some argue that developing strong public health infrastructures in developing countries will have a much greater impact on improving health than focusing funds on specific health issues (Garrett 2007).

NGOs tend to focus on specific health problems (e.g. American Cancer Society), specific health issues such as refugee health or medical care for the underserved (e.g. Doctors without Borders), and specific populations (e.g. drug users and sex workers). Often they can be more effective in reaching vulnerable populations and addressing specific health problems and issues because they are closer to the problem than health professionals who must handle a broad range of concerns. Public health programmes can increase their cost-effectiveness by cooperating with NGOs in addressing specific issues, health problems, and populations.

Industry is often viewed as part of the problem. Public health needs to convince industry to temper its profit motive to incorporate responsible citizenship at all levels. Certainly, industry is frequently a significant contributor to public health problems (e.g. air and water pollution). On the other hand, economic development can lead to an improved economic situation that reduces poverty and benefits all of society. However, industry, particularly the advertising industry, has clearly demonstrated that they are better at creating demand and influencing lifestyles than public health professionals. Thus, it behoves public health organizations to learn from industry and to work with industry to develop and implement healthy economic growth, while safeguarding the environment and benefiting the public.

Private support greatly benefited public health in the twentieth century. The challenge for the twenty-first century is for public health and private support to agree on the most effective use of private funds for achieving the greatest public health advances.

Social activism

Action by groups within society has led to improvements in the health of the public. Social activism by workers and others in the nineteenth and early twentieth century in England and the United States resulted in improved working conditions for workers in a variety of industries and to the development of the field of occupational health. More recently, social activism by social groups adversely affected by HIV/AIDS led to the policy to provide access to treatment for all with HIV infection and the need to recognize the human rights of marginalized groups in both developed and developing countries. Demands for better health conditions led by society itself are most likely to result in positive changes.

The future of public health

Public health does not lack challenges requiring solutions. Poverty is the major cause of poor health globally, yet income disparities in most countries of the world are growing. Developing countries must continue to cope with infectious diseases while confronting the epidemic of NCDs, further compounded by the threat of emerging diseases such as new variants of influenza. Rapid communications and transportation greatly increase the likelihood that local problems will quickly become global problems. This underscores the urgent need for much better international cooperation. An increasing proportion of the world's population will live longer. We have been successful at adding 'years to life', but chronic diseases such as Alzheimer's have reduced the quality of some of the years of life added. We must now concentrate on adding 'life to years', helping older people to continue to be healthy and productive.

We cannot afford to continue to ignore the quality of the environment. Continuing contamination of the air and water will not only cause and/or exacerbate chronic and infectious diseases, but will also compromise global food production. The world's population is still growing and together with increasing urbanization, will further exacerbate the problem of environmental degradation.

Despite the economic and health advances of the past century, disparities between the rich and the poor in many countries are widening. This gap needs to be narrowed, not at the expense of those who are better-off, but by improving the economic situation and health of the poor and disadvantaged. The rising cost of healthcare will make closing the gap in access to healthcare even more challenging.

Injuries and violence are robbing an increasing number of people of their ability to function and to enjoy a reasonable quality of life. Injuries can be easily prevented through a variety of preventive strategies, including better design of the workplace and tools, as well as behavioural and structural approaches.

Violence and war present a particularly great challenge, and will require new strategies not hitherto widely used in public health. Public health must contribute to strategies to resolve differences between countries by promoting cross-national and international cooperation in confronting global health problems, and contribute to strategies to implement successful conflict resolution.

Public health must convince people and provide the environment that allows them to adopt healthy lifestyles. The major strategies to combat the current epidemic of NCDs are regular exercise, a healthy diet, and development of good health habits.

Much is known about what needs to be done to significantly reduce the incidence of NCDs such as cardiovascular diseases, stroke, and cancer, but much more effective ways are needed to effect the necessary changes in personal and community behaviour, and to promote healthy lifestyles.

Tremendous strides have been made to improve the health of the public, but the challenge to do better remains. In subsequent chapters, public health experts discuss the challenges and potential solutions in detail.

The history and development of public health in developed countries

Christopher Hamlin

Introduction to history and development of public health in developed countries

Much more than is usually realized, public health is both a central and a problematic element of the history of the developed world—here conceived as Europe and the ‘Neo Europes’; that is, the set of nations in broad latitude bands of the northern and southern hemispheres in which European institutions and biota have been particularly successful (Crosby 1986).

Over the last three centuries, health status has changed profoundly in these regions; arguably, it is in terms of health that our lives differ most strikingly from those of our ancestors. We live longer. Affluence and transportation mean most of us are no longer subject to periodic famines, and much less subject to epidemics of deadly infectious diseases, although we are less confident about that than we were two decades ago (Ward and Warren 2007). Most of us do not see life as a continuously painful experience and death as a merciful release, a view that is rather commonly found in books of theology from three centuries ago (Browne 1964).

Our health is adversely affected by aspects of the world we have built and the ways we choose to live individually and communally. A good deal is known about how to prevent those effects even if we do not always do so. Nonetheless, an expectation of health and a preoccupation with it are hallmarks of modernity. The freedom of action that ideally characterizes the lives of individuals in the developed world is predicated on health; so much of the agenda of development concerns health, that this transformation has some claim to be seen as one of the monumental changes in human history. It might be argued that economic and political progress are subordinate to securing health—they are means; health, which surely translates into life, liberty, and the pursuit of happiness, is the end.

Surprisingly, the history of public health is under-studied. There remain vast gaps in empirical knowledge, and relatively little comparative work (but see Baldwin 1999; Porter 1999; Kunitz 2007). Public health has sometimes seemed to historians a marginal and uncontroversial function of modern society. After all, we provide medicine, collect and evaluate demographic data, test water, and

keep cities clean in roughly similar ways, according to the conventions of science, technology, and public administration that developed mainly in the nineteenth century. This view partly reflects a distortion of the history of public health by the modern professions and institutions of public health, which have often found it prudent to reduce the significance of the fact that they are necessarily political, even if their business is politics by medical means.

‘Public health’ is conceived broadly in this chapter. It is concerned with the general questions of how, why, and in what manners states came to take an interest in the peoples’ health. The questions of what ‘health’ is, of what we mean by ‘public’, and of what we understand to be the proper domain of ‘public health’ remain contested matters. To define public health as that part of health that is the responsibility of the state does not help: what constitutes the state, and what are presumed to be state responsibilities vary in time and place. However broadly or narrowly we define ‘health’, it will be clear that many public actions affect the public’s health, yet may not necessarily be seen as belonging to the domain of ‘public health’.

An examination of actions taken in the name of protecting or improving the health of the public will illuminate the enigmatic relationship between that universal goal, the health of the public, and public health as an institution—as a profession, science, component of public administration. It will also address matters of moral and political philosophy (Rosen 1958; Fee 1993; Porter 1999), for, ultimately, a history of public health is necessarily part of an ongoing conversation about a programme of social change that is both rational and moral.

Themes and problems in the history of public health

It will help at the outset to recognize several of the most troublesome issues that face any historian of public health. Among these are the following:

1. The units of public health: states and publics:

- ♦ *The public and the state*: the state, concerned with population, may arrive at different health-related policies from a public sphere of groups of citizens, carrying out a rational and critical dialogue among equals (Sturdy 2002). Even when widely

accepted agendas of state responsibility arose, not every state was in the position to act on them. Within the state, the focus of public health was quite often at the local rather than the central level, but responsibility and jurisdiction were often unclear or overlapping. Furthermore, the state may not be the optimal unit for addressing problems which are global such as epidemic infections.

- ◆ *Goals of the state:* although health is now thought of in terms of the biological well-being of individuals, in the past, the goals of programmes of public health have occasionally been directed at ensuring a good supply of labour or of soldiers, control of excess population, protection of elites, enhancement of the genetic stock of a population, or environmental stability.

2. The condition that is truly health:

- ◆ *The definition of health:* the combating of epidemic infectious diseases has often seemed to be the core of public health. Beyond these, questions arise as to the level and kind of physical and mental well-being the state should guarantee or require of its citizens, and of the status of health vis-à-vis other sources of imperatives such as the market, the environment, or individual liberty.
- ◆ *The problem of causation of disease:* in a broad sense, diseases have many causes—personal, social, cultural, political, and economic, as well as biological. Among the multiple antecedents that converge to produce an epidemic or endemic disease, there are numerous opportunities to intervene (MacMahon and Pugh 1970, chapter 2). Notions of rights that must be respected, or of political or technical practicality, narrow that list. Discussion of cause has often included notions of responsibility or preventability—of where in a social system there is flexibility, of who or what must change to prevent disease.
- ◆ *Equality and rights—race, class, gender:* the idea of ‘health for all’ disguises the fact that the interests of the so-called public have not always been the interests of all of its members. Public health actions have often reflected, and sometimes exacerbated, a view of the world in which some groups were seen primarily as perpetrators and others as victims. Often, views of the standards of health that were properly matters for the state varied with respect to different groups: key divisions were by sex, by age (infants, working adults, and the aged all had a different status), by wealth, and by race, religion, or historical heritage (indigenous people had a different status from colonial rulers). Whether the public’s response to disease was to advise, aid, or condemn, or to imprison, banish, or kill, reflected the allocation of rights and the distribution of power more than the status of the biological threat.

3. The health that is truly public:

- ◆ *Health and public health:* most modern states have in principle distinguished aspects of health that are the business of the public from those that are for the individual to pursue in the medical marketplace, although the borders have been drawn in many different ways.
- ◆ *Medical and non-medical public health:* although public health has evolved into an ancillary medical science, with occasional

involvement of engineering and the social sciences, the fact that health has been improved by many non-medical factors—prosperity, town planning, architecture, religious and humanitarian charity, the power of organized labour, and even the enlargement of political or economic rights—suggests that any comprehensive account of improved health must include these factors.

- ◆ *Health as authority:* given the amorphous nature of the concept of health and its status as the supreme good of human existence, it has been attractive as an imperative for political action. If other ‘reasons of state’ carry more immediacy, public health often has had better claim to the moral high ground because it is seen to be universal and apolitical.

These issues are too many to address fully, but they inform what follows. The history of public health in the developed world can be conceived in terms of three relatively distinct missions: public health as a reaction to epidemics, as a form of police, and as a means of human betterment. Public health was initially reactive; faced with epidemic disease, early modern European states closed borders and ports, instituted fumigation, shut down ‘dangerous’ trades, and isolated victims. Second, public health acted as a form of police. Wherever humans live in communities, customs arise for the regulation of behaviour and the maintenance of the communal environment. Gradually, much of the enforcement of community standards became medical. The control of food adulteration or prostitution, of the indigent and the transient, or concern over dung or smoke overlapped with the control of epidemics, but went well beyond it, and occurred in normal as well as in epidemic times.

Finally, public health became a proactive political vision for improvement of the health of all. Well into the nineteenth century, the view remained common that high urban or infant death rates were inevitable. A proactive public health involved the determination that *normal* conditions of health, if they could be improved, were not *acceptable* conditions of health. This shift was partly due to technical achievements—such as smallpox inoculation, and later, vaccination—and to better demographic information, but it rested on changed conceptions of human rights coupled with greater technical and economic optimism. Such visions sustained the building of comprehensive urban water and sewerage systems before there was wide acceptance that these needed to be universal features of cities. Such visions have periodically led public health to venture beyond traditional medical bounds, to recognize, for example, nuclear warfare or gun violence as public health problems.

The public health of epidemic crisis: reaction

Regardless of their virulence and pervasiveness, epidemic and, even more so, endemic diseases do not necessarily arouse comment or action—they may simply be acknowledged as part of life. For the public to decide to fight an epidemic, it must be sufficiently concerned and believe it can do something to mitigate the problem. While a belief in *the possibility of effective action* is a prerequisite for public health, an intriguing question in its history is the emergence of this belief. It does not coincide with the replacement of the supernatural by naturalistic explanations

of disease causation. ‘Will-of-God’ explanations of disease have sometimes incited public action, but on other occasions implied abject resignation.

Similarly, naturalistic explanations—attributing epidemics to a mysterious element in the atmosphere or, as in the case of classical conceptions of smallpox, to a normal process of fermentation in the growing body—have on some occasions been taken as proof that we can do nothing beyond giving supportive care and on other occasions have sanctioned preventive public action. In each case, assessments of technical and political practicality are mixed with assessments of propriety: is taking such action part of our cultural destiny?

These issues are already evident in the first European account of a widely fatal epidemic, the unidentified plague that struck Athens in 430 BC. Athenians both recognized contagion and acknowledged a duty to aid the afflicted, as Thucydides informs us, but these recognitions did not translate into expectations of prevention, mitigation, or escape (Thucydides 1950; Longrigg 1992; Carmichael 1993; Nutton 2000). Few fled; on the contrary, the epidemic was exacerbated by an influx from the countryside. Although it was appreciated that those who survived the disease were unlikely to be affected again, the main response was to accept one’s fate. The disease was attributed to the seasons as well as to the gods, and was said to have been prophesied. Such resignation would be central to the moral philosophies of the Roman world, Stoicism and Epicureanism, both of which taught one to accept what was fated or necessary (Veyne 1987). Later writers in the Christian world attributed the purported failure of Islam to take active steps against plague to such an outlook. Although classical Islamic doctors had developed a science of hygiene to a remarkable degree (Gori 2002), it did not follow that this had implications for intervention in an epidemic: if plague came, that was Allah’s will. To fight it would be futile and impious; one’s duty was to trust (Dols 1977; Conrad 1992; but see ibn Ridwān 1984).

In contrast, the common response to epidemic disease in the late medieval Christian Latin countries would come to be activism. There was hope that one could prevent disease from taking hold in a community, extinguish it if it did, or at least avoid it personally. This activism had many sources. In the Old and New Testaments, disease had a multiplicity of significations. It represented the dispensation of God to an individual, perhaps as punishment or a test. To act against disease by intervening to help others stricken by a dangerous epidemic was an act of devotion. If one died in such a situation, it was a sign of grace; if one did not die, and helped to save others, this was equally a sign of grace. The laws of hygiene in the Pentateuch permitted a naturalistic interpretation of disease. Unclean acts or other transgressions, such as failing to isolate lepers from society, generated the retribution of disease through divinely appointed secondary or natural causes (Douglas 1966; Winslow 1943/1980; Amundsen and Ferngren 1986; Dorff 1986; Lieber 2000).

The two diseases that were most public in medieval Europe were leprosy and plague. Although it is difficult to assess the number of lepers in medieval Europe, the common view is of vast overreaction in terms of both investment in institutions—there were said to be several thousand leprosaria—and the detection and isolation of cases. In keeping with the prominence of leprosy in the Bible, the professionals who diagnosed it were churchmen, not medical men. The leprosy diagnosis was a loose one; it might be based on

skin blemishes alone. Often it led to the expulsion of the victim from ecclesiastical and civil society. Subsequently, no one was to touch or come near the leper or to touch what the leper touched. The theory of contagion provided the rationale for such action, but Skisnes (1973) has argued that the clinical characteristics of the disease itself—for example, its slow development, the visible disfigurement it produced—triggered such a reaction (Brody 1974; Richards 1977; Carmichael 1997; Touati 2000).

The prototypical institutional responses to epidemic disease, however, were those that arose in response to plague. The first wave of plague, the ‘Black Death’, spread across Europe from 1347–1353. Thereafter the disease returned to most areas about once every two decades for the next three centuries. Case-fatality rates appeared high, ranging from 30 to nearly 100 per cent depending on the strain of ‘plague’ (the identity of the microbe has been questioned) (Nutton 2008; Benedictow 2010; Cohn 2010), the means of transmission, and the immunological state of the population. Plague and accompanying diseases reduced the European population by a third or more in the fourteenth century and were responsible for the slowness of population growth during the following two centuries. As with leprosy, the aetiology of plague, and the associated means of prevention and mitigation of the disease were conceived in terms of divine will *and* natural processes (Nohl 1926; Ziegler 1969; Cohn 2010).

It is clear that in many communities plague could not be reconciled with the usual course of events, but indicated some fundamental violation of the cosmos. Boccaccio (1955), whose *Decameron* is a document on the Black Death, testifies to one form of activism—a discarding of social convention and religious duty, a devil-may-care indulgence in the present founded on the recognition that life was short and the future uncertain. Those with the means often fled plague-ridden places. Others, taking the view that the plague reflected God’s just anger with hopelessly corrupt civil and ecclesiastical authority, saw a clear need to take charge of matters temporal and spiritual, to cleanse themselves, the state, and the church. Righteousness would end the plague.

Thus, the plague precipitated a social crisis, as would epidemics of other diseases in subsequent centuries. Beyond the massive disruption caused by high mortality and morbidity and an interruption of commerce and industry, the loss of faith in the conventions and institutions of society was a critical blow. Why respect property, family, or communal obligations, pay taxes, invest money, or tolerate rivals and others? Latent tensions within society had an excuse to become active.

When people acted precipitately and independently, civil and ecclesiastical institutions were threatened, and in their responses, we clearly see the emergence of public health as a form of public authority. For a state, to act in a crisis was to keep the state going; one maintained authority by acting authoritatively. If some state actions were rational in terms of the naturalistic aspects of theories of the plague, preserving the viability of civic authority itself was probably the key issue.

Unfortunately the source of hope, and mode of activism, was often blame. From the ‘Black Death’ onward, the fragility of pluralistic communities was overstrained as the epidemic was attributed to deliberate actions, accidental modes of being, or mere existence of some minority. The minorities might be foreigners, the poor, or Jews, and the actions against them included sequestration, expulsion, or even slaughter (Ziegler 1969). Such actions

were often populist; they arose locally, and had often to be suppressed by national authorities. While it was easy to enlist conceptions of contagion as warrant for such actions, there were plenty of other explanatory options involving appeals to natural processes of disease transmission and generation as well as divine visitation.

Amidst episodes of civil disorder, there arose, particularly in the early modern Italian city-states, relatively successful approaches to plague prevention and control that were the forerunners of modern means of controlling epidemic outbreaks. They included the development of the 40-day hold on ships or other traffic coming from potentially infected places (quarantine), the isolation of victims (and families of victims), and numerous means of purifying the air and/or destroying contamination: bonfires, burning sulphur, burning clothes and bedding, washing surfaces with lime or vinegar, and killing or removing urban animals. Such actions were predicated on an understanding that the disease moved from place to place through some media, possibly involving person-to-person contact.

Although the eclecticism of this response reflected uncertainty about how plague spread, the actions do show a responsive civil authority (Cipolla 1979, 1992; Carmichael 1986; Cohn 2010). Indeed, in some ways plague prevention initiatives were themselves a means of state growth. Plague control required officials to oversee quarantine or isolation procedures. It required a staff to disinfect, and a structure to gather information on health conditions at remote ends of the state. An embassy, which in the high Middle Ages signified an official visit by one state to another, became the permanent presence of one state in the territory of another in the Italian city-states. Its initial purpose was to monitor the public health in the host country and to send word home if plague broke out (Cipolla 1981; Slack 1985).

Plague set the template for the mix of responses and reactions to other disease epidemics. These included flight, the exacerbation of social tensions, a heightening of religious seriousness, and pragmatic efforts to disinfect people, places, goods, or the environment, and to isolate victims or potentially contagious strangers. The theoretical frameworks to justify such actions included atmospheric factors ranging from hypothetical geophysical aberrations to local vitiation from decomposing matter, and various forms of interpersonal transmission. Before the nineteenth century, contagionist and environmental explanations were rarely mutually exclusive as factors implicated in disease (Pelling 2001; Kinzelbach 2006).

The patterns were repeated during the cholera pandemics which first reached Europe in the early 1830s. These brought forth accusations by the poor that the rich were poisoning them (and by the rich that the poor wantonly persisted in living in disease-nurturing squalor). They also engendered calls for public fasts, pure living, and declamations against sinful society, and a variety of attempts to disinfect, quarantine, and isolate (Briggs 1961; Rosenberg 1962; McGrew 1965; Durey 1979; Delaporte 1986; Richardson 1988; Evans 1990; Snowden 1995; Hamlin 2009). Often a key demarcator of class was the very possibility of flight. In nineteenth-century America, the response to yellow fever and malaria was the abandonment of cities during the summer by those who could afford to do so (Ellis 1992; Humphreys 1992). The summer home, in cooler, cleaner, and higher ground, became a mark of upper-middle-class life.

Significant alterations of that pattern came through efforts to control three other diseases: venereal diseases (particularly

syphilis), smallpox, and a mix of diseases including typhus, typhoid, relapsing fever, and ill-other defined conditions, collectively known as continued fever (or just 'fever').

Whether syphilis came to Europe from America or Africa, or had been present in Europe in a milder form has been much debated. What is clear is that a virulent epidemic often known as the French disease or pox began to spread quickly in the last years of the fifteenth century, and can be traced to the intercourse between Italian prostitutes and French and Spanish soldiers during the siege of Naples in 1494. The connection between the disease and sex was made quickly, partly because the initial signs and symptoms affected the external genitalia. In contrast to plague or leprosy, syphilis represented a serious epidemic disease that constituted a state, rather than a municipal, problem: it affected military strength, but was not susceptible to large-scale public action. It was further complicated by having variable symptoms and effects, a long often silent clinical course, and variability in contagiousness and virulence.

To control syphilis, states had to prevail on individuals to avoid behaviours that spread the disease. One might expect the moral opprobrium related to contracting a disease usually acquired through illicit sexual contact to have had some role in discouraging such practices, but it did not. For an adventurous young man, catching the pox was a cost of doing business, even a badge of achievement. The disease was deemed curable, chiefly through mercurial treatments. Although there are suggestions that by the eighteenth century syphilis had become something to hide, such was not the case during the sixteenth century, when the disease was spreading rapidly (Arrizabalaga 1993, 1997).

State attention shifted from cure to prevention only in the eighteenth century; partly because syphilis was becoming more clearly distinguished from other venereal conditions and as the varied manifestations of tertiary syphilis were becoming more evident. The priority European states placed on syphilis as a public problem differed but their approaches did not vary greatly: the disease was to be controlled by regulating prostitutes, who were regarded as the reservoir that maintained the contagion. While such approaches may have had a significant effect in controlling the disease, they exposed tensions between state and individual rights that have since become common in public health.

Such conflicts developed first in the United Kingdom following the first Contagious Diseases Act of 1862, even though its programme against venereal disease was much smaller than that of France, where regulation of prostitution was a central feature of public hygiene (Baldwin 1999). The British Act allowed the police in designated garrison towns to arrest and inspect women presumed to be prostitutes and to confine infected women in hospital. It led to a sustained campaign for repeal, which was ultimately successful in 1885. The repealers represented a broad coalition: some objected that the legislation was morally indefensible because it acquiesced in the immoral industry of prostitution, others that it singled out women whereas the men who used the services of prostitutes were equally responsible for the problem, while still others objected that the practice of arresting women was arbitrary and stigmatized working-class women who were not prostitutes (Walkowitz 1980; McHugh 1982).

The problem that the British parliament faced stemmed from liberal principles of human rights. Ironically, the Contagious Diseases Act had been touted as respecting rights—the rights of

men: the state would inspect women because male soldiers and sailors would not put up with genital inspection. Nor should they be expected to in a state in which the male franchise was broadening and the public was becoming increasingly uneasy with declarations that part of its population existed as cannon fodder. But recognizing the rights of men thus highlighted the fact that the same were not accorded to women.

The issues that arose in combating venereal diseases surfaced in a more general way with smallpox. To the ninth-century doctor Al-Razi, smallpox had been a particularly dangerous stage of normal growth (Clendening 1942), but by the eighteenth century, it often accounted for 10–15 per cent of deaths. It was then widely recognized as a contagious disease of childhood. Many parents intentionally exposed their young children to it: sooner or later, one would be exposed, and the older child who died from it was a multi-year investment lost, while the younger one who survived was subsequently immune.

In many parts of the world, it was recognized that inducing smallpox by some means made it significantly less virulent. Mortality rates might drop from 25 per cent or more to a few per cent. Notwithstanding assertions that such practice defied providence and appeared counter-intuitive, such logic and experience had much to do with the relatively rapid acceptance of inoculation after 1721, when it was introduced into Western Europe by Lady Mary Wortley Montagu, a well-connected aristocrat who had observed the process in Turkey. It was first taken up in the British Isles; its subsequent spread resulted from the patronage of royalty and nobility, increases in the safety of the procedure, especially when carried out by the most highly skilled practitioners, and the acquiescence of at least a segment of the medical profession (Miller 1957; Razzell 1977; Hopkins 2002).

In 1798, the English practitioner Edward Jenner made immunization significantly safer by introducing the practice of vaccination with cowpox. Increasingly, smallpox prevention, hitherto a personal matter, became a state concern. Presumably, the institutions that orchestrated quarantines could also ensure universal vaccination. But here too there was ambiguity: in whose interests were vaccination programmes to be undertaken? England began offering free vaccination in 1840, made it compulsory in 1853, and instituted fines for non-compliance in 1873. The initial assumption that all would take advantage of this free medical service proved unfounded; as the authorities sought to give the vaccination laws more teeth, they encountered growing opposition and decreasing rates of compliance.

In 1898, anti-vaccinationists gained permission for conscientious objectors to forgo having their children vaccinated. The opposition was able to show that the dangerous procedure was not carried out everywhere with sufficient skill or care, and a real decline in smallpox meant decreasing risk to the unvaccinated. But mandatory vaccination also exposed underlying tension between the state and the public: in an atmosphere of distrust of the state, the more insistent the state became, the more convinced the public became that the state's actions were not in their interests (Porter and Porter 1988; Baldwin 1999; Durbach 2005; Brunton 2008).

It is important to emphasize that for most of the history of the West, efforts to combat epidemic disease were not reflective of a sense of obligation to the health of individuals. The welfare of individual subjects was incidental. Although states devoted substantial

resources to enforcing quarantines and other health regulations (and absorbed considerable costs in lost commerce), it would be misleading to think of them acting in some quasi-contractual way as agents for groups of individuals who had recognized that public actions were necessary to secure their own health. Although many places had town or parish doctors, and there was often an expectation that the state take some steps to protect the welfare of its subjects (such as making food affordable in times of dearth), early modern political theorists recognized no general obligation of the state to protect the health of individuals. What was at risk in an epidemic was the state itself: the collection of taxes, the maintenance of defence, the continuance of commerce, and even the orderly transfer of property at a time of high mortality.

Perhaps nowhere was the tension between individual and state so great as in the combating of what was called 'continued fever'. Typhus, typhoid, relapsing fever, and yellow fever were among the several epidemic diseases that appeared or became increasingly prominent in the aftermath of the Black Death. This 'continued' fever (malaria was generally distinguished as 'intermittent' fever) was endemic as well as epidemic, and amidst vast disagreement about classification and cause, there was general agreement about its frequent association with social catastrophe and squalor—with war, jails, pestilence, famine, and overcrowded slums (Wilson 1978; Smith 1981; Hamlin 1998, 2006; Geary 2004). Although it was often associated with class, it did not limit itself to the poor. Many theorists believed the fever could spread from poor to rich, whether by person-to-person contact or by diffusion through some environmental medium from hovels and slums to mansions. But, as would later be the case with tuberculous diseases, it was not clear whether one could disentangle any single factor from the many conditions of poverty, nor did medical men necessarily think it made sense to try.

The public action that might have been taken was the comprehensive improvement of living conditions—the prevention of overcrowded dwellings; the insurance of sufficient food, fuel, and clothing; the provision of personal and environmental cleanliness, a safe work place, and a non-exhausting work day—in short, all the physical and social changes that would produce a sound human being. Yet, such far-reaching actions to defend the state also threatened to transform it and in essential ways—in its social distinctions, its institutions of property, even in the political rights it recognized. When the young Prussian radical doctors Rudolph Virchow and Sebastian Neumann investigated a typhus outbreak in Silesia in 1848, they argued that liberal political and economic reforms were the antidote to the squalor which caused the epidemic (Rosen 1947). Irish physicians made similar diagnoses in the pre-famine years, even proposing a 'political medicine' in which health outcomes would be a major consideration in public policy (Hamlin 2011).

The public health of communal life: police

Beyond the response to epidemics, Western societies had from early times taken steps to regulate their communities for the common good or public peace. By the eighteenth century, the term generally used for such efforts was 'police', but the control of crime was only a small part of it. It generally referred to matters of internal public order; that is, to all aspects of government other than

military and diplomatic affairs, the raising of funds, import and export duties, matters of land tenure, and civil litigation. Box 1.2.1 lists common police functions.

Sometimes, doctors were involved in this enforcement, and some of these matters were overtly medical, but at least as often, doctors were part of the domain to be regulated.

The issues under the heading of police comprised problems at various levels: for individuals as town dwellers or as adjoining property owners within a neighbourhood, for towns as corporate entities, and for regional or national states. Public health, in the sense of a recognized obligation to protect the health of the people through public regulation, was only rarely the rationale for police, although improvement in the public's health was likely often a consequence of police action. In some cases, 'police' involved public means for the resolution of disputes between individuals as property owners, such as those that arose when drainage, smoke, or dung encroached on another's premises. At a municipal level, a widespread concern with the policing of commerce and manufacture reflected the town's dependence on its markets. The privileges of trade and industry within a town were rarely free; the concern with the quality of foods and drugs was less a matter of consumers' health than of fair competition, consumer satisfaction, and maintenance of the market's good reputation. Finally, at the state level, concern with midwifery, nutrition, or demographic statistics did not necessarily reflect concern with individuals' health. Early modern statecraft equated state strength with population.

The character of institutions of police varied considerably, although most medieval (and ancient) European towns had some kind of institution(s) to carry out the tasks listed earlier (Hope and Marshall 2000). Typically, these mirrored the political structure of the state. In medieval Islamic towns, a *muhtasib*, an

appointee of the caliph oversaw public morals and commerce, but also regulated medical and veterinary practice, refuse disposal, water supply, the cleansing of the public baths, and the licensing of prostitutes (Karmi 1981; López-Piñero 1981; Palmer 1981). In England, where the state was weak and towns strong, police institutions were more community based; this bottom-up character of dispute resolution would evolve into common law. Among medieval English institutions of local government were the *leet* juries (groups of citizens who biannually perambulated through the town and 'presented' the nuisances they found to the magistrates, who would order abatement), and the courts of sewers, which acted similarly in trying to resolve conflicts about drainage. Whenever a landowner altered drainage patterns, others were affected, often deleteriously. The sewers court was a means of minimizing those adverse effects and compensating for damage when they were unavoidable. In a similar way, London's Assize of Nuisances managed disputes between neighbours about the location and cleansing of privies (Webb and Webb 1922; Redlich and Hirst 1970; Chew and Kellaway 1973; Leongard 1989; Novak 1996). The concept of 'nuisance', if not the term, underlay much of the work of public police. In the Anglo-French tradition, a 'nuisance' was an accusation, subsequently backed by a legal determination, that actions on one person's property or in the public domain annoyed and/or interfered with the enjoyment of another's rights (Blackstone 1892; Novak 1996; Hamlin 2002). Common forms of 'nuisance' included conditions offensive to health and sensibility, such as concentrations of pig manure or butchers' waste, as well as antisocial behaviour.

The business of the public police did affect health in many ways and also covered much of what would later belong to the domain of public health. The priority, however, was usually with amenity, morality, and conflict resolution. However, although the motives and contexts of police initiatives were broader than public health matters, there were overlaps in both practice and theory. The police institutions in late medieval Italian city-states evolved from means of plague response (Carmichael 1986; Cohn 2010), and almost always, a poorly administered town was looked upon as ripe for an epidemic. Moreover, within Hippocratic and Galenic frameworks, amenity was not clearly distinct from health: to feel well was to be well; unpleasant sights or smells, noises, or incidents, even if they did not lead to disease, constituted both a form of trespass and an assault on health (Carlin 2005). Concepts of specific diseases and vectors were far in the future. Notwithstanding the occasional speculation, such as that of the sixteenth-century Italian doctor Girolamo Fracastoro that each disease might be the product of an invisible living seed, most medical men were not thinking about individual diseases in a way that would encourage them to look for discrete agents. Because amenity, order, and health were so closely linked, a medical rationale could provide a basis for social action on behalf of a community.

Too little is known about the operation of these police institutions. What is known suggests that their performance varied enormously. It also suggests that the popular image of the pre-modern town as filthy and ungoverned is misleading. There may well have been filth on the streets, but clearly in some cases it was put there at prescribed hours prior to the rounds of the municipal street sweepers, who would collect it for manure or otherwise dispose of it. Many urban cottage industries—dyeing, soap making, the treating of leather or textiles—did use unpleasant

Box 1.2.1 Police functions

- ◆ The enforcement of basic rules of public behaviour.
- ◆ The enforcement of standards of building construction and use, with regard to noxious trades and basic sanitation.
- ◆ The care for the poor, the disabled, and for abandoned children or orphans.
- ◆ The regulation of hours and modes of work.
- ◆ The conduct of markets and the quality of the commodities sold in them.
- ◆ The regulation of marriage and midwifery.
- ◆ The supply of water to people and the treatment of cattle and other animals.
- ◆ The inspection and regulation of transients and prostitutes.
- ◆ The appropriate disposal of the dead, both human and animal.
- ◆ The prevention of fire and injury.
- ◆ The investigation of accidental deaths and other forensic matters.
- ◆ The maintenance of population statistics.
- ◆ The regulation of medical practice.

animal products; complaints about them often reflect the struggle between classes for control of the urban environment, with wealthy merchants or professionals appealing to supposedly universal standards of sensibility and health to enhance their status over those who worked in what Guillerme calls the fermentation industries (Guillerme 1988).

Two examples of the ongoing legacy of such institutions of police can be seen in the regulation of the food supply and the evolution of the concept of 'nuisances' in Anglo-American public health. The fight for pure food and drugs that developed in the later nineteenth century is often seen as an early manifestation of consumerism, and equally, the product of advances in chemistry, microscopy, and bacteriology as applied to foods. Currently, regulation of the food supply is one of the most common duties of public health departments—efficient inspection of meat- and milk-processing plants and institutional kitchens is seen as an essential component of a civilized society. There were changes in the late nineteenth century in the recognition of a wider range of food contaminants, and due to the need to grapple with a more ingenious group of food adulterers, whose doings were better hidden by an increasingly complicated system of food production and distribution. But the concerns of consumers with food safety and their view that food inspection was a duty of government was old and widely shared. The concern of many medieval food inspection officers was with honest weights and measures, but quality was always implicit—the just measure did not satisfy if the ale was diluted. Although there might not have always been objective ways of determining food quality, consumers knew and enforced a moral economy on transgressing vendors: The records of civil discord are packed with the trashing of shops and the thrashing of vendors (Thompson 1971).

Traditions of market regulation affected public health more broadly. Concern about water quality in metropolitan London, for example, reflected consumer outrage at high prices and poor quality and quantity of the water well before there was any epidemiological evidence of it causing cholera. Equally, public willingness to accept that epidemiological evidence was tied to anger at paying too much for an irregular and visibly dirty water supply (Hamlin 1990; Taylor and Trentmann 2005). It is also likely, although difficult to show, that the ready acceptance of the new scientific forms of food inspection in the late nineteenth century reflected consumer expectations that the service was necessary and appropriate for government to undertake (Waddington 2006).

In the case of environmental nuisances too, institutions of public health took over from long-standing institutions for settling civil disputes. Whereas in earlier centuries the concept had been very broad—including excessive noise, disturbances of the peace, the blocking of customary light—by the mid-nineteenth century, the quintessential nuisance had become urban dung, human and animal, and action against nuisances acquired a basis in statute law that supplemented its status in civil law. Beginning with the first English Nuisances Removal Act of 1846, passed in an expectation of the return of cholera, doctors, and later a new functionary called an inspector of nuisances (later a sanitary inspector), were charged with identifying nuisances and taking steps to have them removed (Wilson 1881; Hamlin 2005). The change from civil to criminal law reflects a recognition that a legal tradition built upon the power of property was ill-suited to a situation in which most property was not occupied by its owners, and equally to a situation in which most people's sensibilities were insufficiently

offended by the particular states of environment presumed to be associated with cholera.

Although this change was an emergency response, its effects were more far reaching. It represented the investing of community standards for health in a permanent institution with enforcement powers, rather than leaving them to be worked out incident-by-incident, through common law. The inspectors of nuisances did not restrict themselves to documented causes of disease, but continued to respond to community complaints, which sometimes were primarily aesthetic. They became the defenders of the ever-rising standards of middle-class life, and however far their activities might stray from any direct relation to disease control, they carried with them the authority of public health imperative (Hamlin 1988, 2005; Kearns 1991).

Towards the end of the nineteenth century, some epidemiologists, recognizing that the tracing of cases and contacts informed by the new science of bacteriology provided a more exact means of disease control, suggested that concern with general environmental quality was an unjustified expense that deflected the attention of public health departments from what really mattered (Cassedy 1962; Rosenkrantz 1974). In some cases, they were effective in severing sanitation and public works from public health, but often they found that the public, who tended to support clean streets and pleasant neighbourhoods, continued to use public health as justification. More common than the wholesale replacement of sanitation by bacteriology was the emergence of what has been called a 'sanitary-bacteriological synthesis' (Barnes 2006). Here too, medical science gave public action a legitimacy that would otherwise have been difficult to create.

The medicalization of public police that these examples suggest was clearly underway by the mid eighteenth century. The concept of medical police first arose in Germany and Austria, later in Scotland, Scandinavia, Italy, and Spain; in France the rough equivalent was *hygiène publique*. In America and in England, the term and concept never really caught on (Carroll 2002). Medicine's rise to prominence reflected an alliance between medical practitioners who sought state patronage and the 'enlightened despots'—rulers who, such as Austria's Joseph II, sought a science of good government that would significantly strengthen their states. Increasingly, rulers like Joseph felt obliged to test their policies against some tenets of rationality; health seemed to offer a well-defined arena of rational government, a set of means to improve the state and to measure the progress of that improvement (Rosen 1974, 2008). As the regulation of personal behaviour could improve the health of soldiers and sailors, why not practise the same techniques on the rest of society? The effect of this medicalization was to move matters of police further from the realm of local social relations and towards an all-encompassing scientific rationality.

The classic text of eighteenth-century medical police is medical professor and public health administrator Johann Peter Frank's six-volume *A System of Complete Medical Police*, which appeared between 1779 and 1819 (Frank 1976). The first two volumes discussed reproductive health, including suggestions for the regulation (and encouragement) of marriage, prenatal care, obstetrical matters, and infant feeding and care. The book then turned to diet, personal habits, public amusements, and healthy buildings. The fourth volume covered public safety from accident prevention to the injuries supposedly inflicted by witches, the fifth volume dealt with safe means of interment, and the sixth with the regulation of the medical profession. In Frank's cameralist view, anything that adversely

affected health was a matter for public policy and an appropriate subject for regulation—rights, traditions, property, and freedom had no status if they interfered with the welfare of the population.

In its most far-reaching definitions, modern public health approaches the domain of a comprehensive police. It also recognizes that a wide range of factors is implicated in health conditions—current public health concerns include the effects of violent entertainment, the prevention of gun violence, and the conditions of the work place. But in modern liberal democracies, much of what Frank saw as the obvious business of the state is deeply problematic. For, in the nineteenth century, public health shifted radically in mission and constituency. It became less a means of maintaining the state, and more a means by which the state served its sovereign citizens with an (increasing) standard of health that they (increasingly) took as a right of citizenship.

The public health of human potential

We often think that health is a service that governments owe their citizens, that what separates past from present is not intent but simply sufficient knowledge of the means to provide that service—this is not so. A public health that is not merely reactive or regulative but which aims to reduce rates of preventable mortality and morbidity as its duty to its populace, is a product of the eighteenth century. It is also one of the most remarkable changes of sensibility in human history. Its causes are complex but poorly understood. Concepts of preventable mortality and excess morbidity required the ability to show that death and illness existed at much higher rates in some places than in others. It required also recognition of some ways to address these conditions.

Although there were a few attempts in seventeenth- and eighteenth-century Europe to determine local bills of mortality, they were too few to provide a basis for comparison. In contrast, by the late nineteenth century, annual mortality rates were an important focus of competition among English towns. The central government's public health officials, notably John Simon, chief medical officer of the Privy Council from 1857–1874, badgered towns with poor showings. Simon and his successors urged them to analyse the reasons for their excess mortality and to take appropriate action (Brand 1965; Lambert 1965; Eyler 1979; Wohl 1983). By the end of the century, and during the twentieth century, reliable morbidity statistics were available to provide a better understanding of the remediable causes of disease. The gathering of such data, and after about 1920 their analysis by modern means of statistical inference, has become a central part of modern public health (Desrosières 1998; Magnello 2002).

The mission of prevention was also tied to a very real growth in knowledge of the means of prevention. The widespread adoption of inoculation, and after 1800, of vaccination for smallpox, was the first clearly effective means to intervene decisively to prevent a deadly disease. Initially through the development of the numerical method and the cultivation of pathological anatomy in the Parisian hospitals in the first decades of the nineteenth century, and subsequently through bacteriological and later serological methods, infectious diseases were distinguished and their discrete causes and vectors identified (Ackerknecht 1967; Bynum 1994). Such recognition ultimately led not only to the 'magic bullet' thinking of vaccine development, but also underwrote campaigns to improve water quality and provide other means of sanitation,

and sometimes, as with tuberculosis and typhoid, programmes to identify, monitor, and regulate carriers.

Yet these factors alone cannot account for the widespread conviction that human health must be significantly improved—they are means, not ends. Despite the significance of effective action against smallpox, it did not imply that all infectious diseases could be controlled through a similar strategy. In most cases, the new medical knowledge did not precede the determination to improve the health of all, but was developed in the process of achieving that goal. A great deal of success was achieved despite quite erroneous conceptions of the nature of the diseases and their causes. The great sanitary campaign against urban filth (based on a vague concept of pathogenic miasms) is the best-known example (Barnes 2006).

Recognition of differential mortality was not new in the early 1800s, but it did not necessarily spur action. The mortality penalty associated with poverty, infancy, and urban living was regarded by some as a necessary corrective to the overfecundity of the countryside (Sadler 1830; Weyland 1816/1968). Even humane and optimistic writers saw infant mortality rates of 25 per cent or more as providential (Robertson 1827).

In contrast, the modern sensibility admits no justifiable reason (beyond, perhaps, the climatic factors that determine the range of some disease vectors) for differential mortality or morbidity. These changes in sensibilities towards state provision can be divided into three periods: an age of liberalism from 1790–1880; a golden age of public health to 1970; and a more confusing post-modern period in the last four decades, which may, at least in its most positive aspects, be seen as a return to liberalism.

The age of liberalism: health in the name of the people, 1790–1880

The social and intellectual movement known as liberalism, which began to prevail in the second half of the eighteenth century, included a wide range of philosophical, political, economic, and religious ideas, but at its heart were notions of individual freedom and responsibility, and usually, of equality in some form. In 1890, when John Simon, England's first chief medical officer and a pioneer of state medicine, surveyed progress in public health during the past two centuries in his *English Sanitary Institutions*, he included a lengthy chapter on the 'New Humanity'. In it, he covered the antislavery movement, the rise of Methodism, growing concern about cruelty to criminals and animals, legislation promoting religious freedom, the replacement of patronage by principle as the motor of parliamentary democracy, the introduction of free markets, the rationalization of criminal and civil law, and efforts towards international peace. Simon saw little need to explain how this concerned public health; he was sketching a fundamental change in 'feeling' that underlay changes in public health policy.

No longer were humans so much cannon fodder; the best policies were those which maximized 'human worth and welfare' (Simon 1890; compare with Pettenkofer 1941; Coleman 1974; Haskell 1985).

What Simon recognized was that with the granting of equal political and economic rights and responsibilities, it was no longer possible to see health status constrained by class, race, or sex. Nineteenth-century French and English liberals recognized that

some—particularly women, children, and the poor—still suffered ill health disproportionately, but they saw such consequences as incidental, accidental, and increasingly, as unnecessary and objectionable: in principle, all had an equal claim to whatever human and health rights a society was prepared to recognize. This change in feeling was both the cause and effect of the widening distribution of political power.

And yet liberalism was no clear and compact doctrine, and its implications for public health were, and still are, by no means clear. Few of the pioneers of liberal political theory had bothered to translate human rights into terms of health. They wrote mainly with middle-class men in mind, and saw the threats to life, liberty, and property as political rather than biosocial. The expansion (or translation) of political rights into rights to health was gradual, piecemeal (it has never been the rallying cry of revolution), complicated, and even fundamentally conflictual—it was, and is, not always the case that the choices free individuals make will protect the public's health, or even their own. Concern with public health arose accidentally, and in different ways and at different times in the developed nations. At the beginning of the twenty-first century, an obligation to maintain and/or improve the health of all citizens exists only in varying degrees.

Many early liberals found health rights hard to recognize because so much of public health had been closely associated with the medical police functions of an overbearing state. In revolutionary France, the first instinct was to free the market in medical practice by abolishing medical licensing, a policy quickly recognized as disastrous for maintaining the armies of citizen-soldiers who were protecting the nation (Foucault 1975; Riley 1987; Weiner 1993; Brockliss and Jones 1997). Even after new, meritocratic, and science-based medical institutions had been established, the cadre of public health researchers that French medicine fostered—at the time, the world's leaders in epidemiology—found it difficult to conceive how their findings of the causes of disease could be translated into preventive legislation. Working and living conditions were dictated by the market; government mandates would induce dependence or simply shift the problem elsewhere. Thus, France was the scientific leader in public health for the first half of the nineteenth century without finding a viable political formula for translating that knowledge into prevention (Coleman 1982; LaBerge 1992).

In early-nineteenth-century Britain, the ideas of T.R. Malthus led a broad range of learned public opinion to similar conclusions. Disease was among the natural checks that kept population within the margins of survival. Successful prevention of disease would be temporary only; it would postpone an inevitable equilibration of the food–population balance that would then need to occur through some other form of catastrophe (Dean 1991; Hamlin 1998). Malthusian sentiment blocked attempts to establish foundling hospitals. Notwithstanding the fact that such institutions were notoriously deadly to their inmates, it was felt that their existence encouraged irresponsible procreation—faced with full economic responsibility for their actions, men would stifle their urges (McClure 1981). Malthusian views were prominent in British policy with regard to Ireland, Scotland, and India.

By 1850, in both France and England, it was no longer possible to maintain faith in the welfare-maximizing actions of a completely free society. A number of factors shattered this faith. First, no government ever adopted the programme of the early

nineteenth-century liberals in full. In Central, Eastern, and Southern Europe, the old concerns of state security continued to govern their public health. In Sweden and later France, concern about a state weakened by depopulation fostered attention to the health and welfare of individuals.

Second, working-class parties, although often generally sympathetic with political liberalism, saw no advantage in economic liberalism. Often, they demanded adherence to the moral economy of the old order, in which governments damped fluctuations in grain prices and enforced the working conditions that craft guilds had established. Most important is that many liberals themselves arrived at a biosocial vision, which recognized that it was impractical, inhumane, and injudicious to impose economic and political responsibilities on people who were biologically incapable of meeting those responsibilities: liberty had biological prerequisites.

These considerations were central to debates in France and Britain in the 1830s and 1840s. Governments in both countries were apprehensive of revolution and wary of an alienated underclass of people who could not be trusted with political rights and seemed immune to the incentives of the market. Such people represented a reservoir of disease, both literal physical disease and metaphorical social disease, that could infect those clinging precariously to the lower rungs of respectability. Reformers proposed to somehow transform these dangerous classes, usually with Bibles, schools, or experimental colonies. Such was the political background against which Edwin Chadwick (1800–1884), secretary of the English bureau charged with overseeing the administration of local poor relief, developed 'the sanitary idea' in the late 1830s (Finer 1952; Lewis 1952; Chadwick 1965; Richards 1980; Hamlin 1998).

Chadwick justified public investment in comprehensive systems of water and sewerage on the grounds that saving lives—particularly of male breadwinners—would be recompensed in lowered costs for the support of widows and orphans. But he also suggested that sanitation would remoralize the underclass, and for many supporters, this was its most attractive feature. Politically, sanitation was a brilliant idea, as every other general reform was deeply controversial: proposals for religion and education were plagued by sectarianism, calls to improve welfare by allowing free trade in grain (leading to lower food prices) ran afoul of powerful agricultural interests, proposals for regulating working conditions were unacceptable to powerful industrial interests. Notwithstanding complaints that towns should be allowed to reform in their own ways and their own good time rather than being forced to adopt Chadwick's technologies and deadlines, sanitation achieved remarkable popularity in nineteenth-century Britain.

In treating insanitation as the universal cause of disease, Chadwick hoped to establish a public health that was truly liberal. He sought to deflect attention from other causes of disease, such as malnutrition and overwork, for these were areas of great potential conflict between public health and liberal policy. For many political theorists, the liberty of the free adult to bargain in the market for labour without state intervention to limit hours or kinds of work was axiomatic. And the need for food was to be the spur for work and self-improvement. Interventions by a 'nanny state' seemed to imply an obligation to the state and to affirm the desirability of dependence and subjugation. There were grounds for such concern: the relations of political status to health were fraught with ambiguity. Frank had written passionately of misery

as a cause of disease amongst the serfs of Austrian Italy, but had not advocated the elimination of serfdom. Virchow argued, in 1848, that liberal political rights were the answer to typhus in Silesia, while in Scotland, W.P. Alison argued the contrary, that too rigorous a liberal regime was the cause of poverty-induced typhus (Frank 1941; Rosen 1947; Weindling 1984; Hamlin 2006).

For about a generation, from 1850–1880, sanitation was unchallenged in Britain as the keystone of improved health. Chadwick's campaigns led to a series of legislative acts—beginning with the Public Health Act of 1848 and culminating with a comprehensive act in 1875—that established state standards for urban sanitation and a bureau of state medicine, staffed by medical officers in central and local units of government and charged with detecting, responding to, and preventing outbreaks of disease (Wohl 1983).

Outside Britain, although the ideals of sanitation might have had similar appeal, they did not warrant the same conclusions about state responsibility or sanitary technology. The English paradigm of a water-centred sanitary system was adopted only in the twentieth century (Simson 1978; Göckjan 1985; Goubert 1989; Labisch 1992; Münch 1993; Ramsey 1994; Melosi 2000; Hennock 2000). Often, the heritage of medical police was more prominent than that of sanitary engineering. Networks of local medical officers to control contagious disease transmission through the regulation of travel and prostitution were important.

Through the 1880s, the United States remained an exceptional case, coming closest to following a policy that an individual's health was a private matter alone. The national government maintained a system of marine hospitals along the coasts and navigable rivers, less for controlling the spread of epidemics than for relieving ports of the burden of caring for sick seamen. In the early 1880s, it established a National Board of Health to advance knowledge on key public health issues, but it was scrapped within a few years on the grounds that public health was the business of individual states and cities (Duffy 1990). Often dominated by rural interests, many state legislatures had little enthusiasm for public health. Louisiana, which established a state board of health to combat yellow fever, was an exception (Ellis 1992). Towns and cities were more active, but often only sporadically, taking steps when faced with epidemics. States that did establish boards of health usually focused on specific problems rather than on public health in general: in Massachusetts, the allotment of pure water resources was a key issue; elsewhere, it was food quality, care for the insane, vital statistics, or the threat of immigrants (Rosenkrantz 1972; Shattuck 1972; Kraut 1994). In Michigan, concern about kerosene quality (it was being adulterated with volatile and explosive petroleum fractions) and arsenical wallpaper dyes spurred the establishment of a state board of health in 1873 (Duffy 1990).

1880–1970: the golden age of public health?

By the 1880s, the liberalism of the first half of the century was giving way to a resurgent statism. The European nations, the United States, and later, Japan competed for colonies and international influence. If the newly liberated or enfranchised had claims to a right to health, they also had a *duty to the state* to be healthy. In most industrialized nations, there was renewed interest in monitoring social conditions.

Although the emerging techniques of empirical social research gave this inquiry the aura of quantitative precision, the surveys disclosed little that was distinctly new about the lives or health of the poor, the usual targets of public health and social reform. Much of it seemed new, however, because it now registered as problematic (Turner 2001). For example, the enormous contribution of infant deaths to total mortality had long been clear, but only towards the end of the century did persistently high infant mortality become a problem in itself as distinct from a general indicator of sanitary conditions. The health conditions of women and of workers began to command attention in a way that they had not done previously (Sellars 1997).

Although these newly recognized public health problems partly reflected the changing distribution of political power, they also reflected anxiety about the nation's vulnerability, and even the decadence of its population. Worried about the strengths of their armies, states such as Britain discovered in the 1890s that too few of those called up were competent to be mobilized, and this was attributed to causes ranging from poor nutrition (coupled with lack of sunlight in smoky cities), to bad sanitation, mothering, and heredity (Soloway 1982; Pick 1989; Porter 1991a, 1999; Stradling and Thorsheim 1999). Epidemics of smallpox following the Franco-Prussian War of 1870 and again in the 1890s disclosed the gaps in vaccination programmes (Baldwin 1999; Brunton 2008), resulting in states redoubling efforts to take responsibility for the immune status of their population (Brandt 1985; Baldwin 1999).

This led to an expanded public health, one highly successful in terms of reduced mortality and morbidity. It was undertaken jointly in the name of the state and the people, but it involved the regulation of an individual's life—home, work, family relations, recreation, sex—that went beyond the medical police of the previous century. From a later standpoint, such intimate regulation of the individual by the state may seem overbearing, but, with some notable exceptions, the populations of developed countries accepted it as legitimate and even desirable.

New diseases, or old diseases that were more prevalent or virulent, new public health institutions, and advances in medical and social science contributed to this new relation between states and people. During the 1860s, a long-standing analogy of disease with fermentation matured into the germ theory of disease as the research of Louis Pasteur and John Tyndall made clear the dependence of fermentation on some microscopic living ferment (Pelling 1978; Worboys 2000). During the 1880s, primarily through the work of emerging German and French schools of determinative bacteriology, it became possible to distinguish many separate microbe species, to ascertain the presence of particular species with some confidence, and therefore, to link individual species with particular diseases (Bulloch 1938). Through serological tests developed in the succeeding decades, the presence of a prior infection could be determined, regardless of the presence of symptoms.

Notwithstanding the increasing recognition of the many ways by which infectious microbes were transmitted from person to person, the effect of the rise of the germ theory was to focus attention on the body that housed and reproduced the germ—for example, the well-digger working through a mild case of typhoid—even when there were alternative strategies (water filtration or, by the second decade of the twentieth century, chlorination) that protected the public reasonably well most of the time (Hamlin 1990; Melosi 2000). The general interest in the human

as germ-bearer and culture medium brought with it an emphasis on labour-intensive case-tracing, of keeping track of those with symptoms of the disease together with those with whom they had contact.

For key diseases like typhoid, syphilis, and tuberculosis, concern with the inspection and regulation of people was exacerbated by the recognition that not all who were infected were symptomatic. The case of 'Typhoid Mary' Mallon, the asymptomatic typhoid carrier who lived for 26 years as an island-bound 'guest' of the City of New York, is notorious, but it was also important in the working out of both legal limits and cultural sensibilities with regard to the trade-off between civil rights and public health (Leavitt 1996). Newly virulent forms of diphtheria and scarlet fever, deadly childhood diseases transmitted person to person or by common domestic media, also gave immediacy to decisive public health intervention.

Such monitoring could not have occurred without a large corpus of local public health officers. It was during the late nineteenth century that public health was identified as a distinct division of medicine and when most developed countries solidified a reasonably complete network of municipal and regional public health officers. Increasingly, these officers worked as part of hierarchical national health establishments to which they reported local health conditions and from which they received expert guidance.

Beginning in the mid 1870s, public doctors started to be specially trained and certified for public health work (Novak 1973; Watkin 1984; Acheson 1991; Porter 1991b). A commitment to public health was increasingly incompatible with ordinary medical practice, not because of its specialized knowledge, but because it was built upon a quite different ethic. There had long been economic tension between public and private medicine in areas of practice such as vaccination, in which public authorities either took over entirely or inadequately compensated private practitioners for services that had traditionally been part of the ordinary medical marketplace (White 1991; Brunton 2008).

But monitoring healthy carriers and those who might be susceptible to disease introduced a new regime of medicine—one which responded to an ethic of public good, even if there were no client-defined complaints. Effectively, bacteriology, epidemiology, and associated measures of immunological status redefined disease away from the patient complaint. The healthy carrier might see no need to seek medical care, but to the public health doctor that person was a social problem. On occasion, private doctors were appealed to for a diagnosis (bronchitis, pneumonia) that would protect one from the health officer's diagnosis of tuberculosis, which would bring loss of employment and social stigma (Smith 1988).

Rivalling the germ theory as the major motif of public health thinking from the 1890s to the 1950s was the application of the emerging science of heredity to the improvement of human populations—the science and practice of eugenics (Paul 1995; Kevles 1995). Whether or not eugenic concerns were the source of the greatest anxiety about the public's health is debatable, but they were the locus of the greatest hope for health progress. Even more than other forms of public health, eugenics exposed a class, and sometimes a racial, division that had long been a part of public health: much public health practice was predicated on a distinction between those, usually the poor, who were seen as the objects of public health efforts and those, often the well-to-do, who

authorized intervention, whether to improve the lot of the poor, to protect 'society', or perhaps even to block the physical or moral contagia that might infect their own class (Kraut 1994; Anderson 1995; Bashford and Hooker 2001; Carlin 2005). Eugenics appealed mainly to those with wealth and power: those others who were to be improved rarely identified heredity as the source of their problems.

Such an attitude is reflected in the most infamous application of the eugenic viewpoint, the attempt by Nazi Germany to exterminate Jews and other 'races' regarded as inferior and unfit to intermarry with so-called 'true Aryans', and even to exist. Although historians' views of the origins of the Holocaust differ, some of the immediate precedents for a state policy of negative eugenics—the prevention of the reproduction of those regarded as unfit—came from the sterilization laws that American states had begun to pass in the first decade of the century. The American laws focused on persistent immorality or criminality, and on what was called 'feeble-mindedness'.

In Germany, the acceptance of sterilization translated rather easily into the acceptance of euthanasia of the permanently institutionalized, and on to the extreme measures of the death camps, which were conceived of as facilities of state medicine. Even during the Holocaust, the prevailing rationality remained that of public health: the trade-off between individual rights and the state's welfare was a part of the working moral world of the public health officer. A campaign against Jews from Eastern Europe had already been rehearsed in typhus control efforts in the preceding generation (Weindling 1999). Just as an excision of cancerous matter might be necessary to maintain the body of the individual, so too an excision of a part of society might be necessary to maintain the health of the nation (Lifton 1986).

The horrors of the extreme version of eugenics practised in Nazi Germany have discredited eugenics to such a degree that it is difficult to recapture how central it seemed to reformers of the left as well as of the far right. It appealed for a number of reasons. First, it explained the failure of prior reforms, particularly sanitation, in effecting the physical and moral renewal of the lower classes.

Second, it seemed to be implied by Darwin's discoveries, which were themselves founded on deep familiarity with the remarkable transformations achieved by scientific agriculturalists in animal breeding. Those discoveries seemed particularly applicable within the utilitarian framework of the new statism: the task of governments was to reverse the trend towards decadence and produce uniform, reliable humans. Such concerns became powerful especially for nations that perceived themselves to be in demographic crisis, such as Sweden, which was experiencing depopulation and persistent tuberculosis, and the United States, where successive groups of immigrants found reasons to deplore the effects on the nation of the next immigrant group (Johannisson 1994; Kraut 1994; Broberg and Roll-Hansen 1996). Finally, it flattered those who held power and prominence by offering a simple explanation of all that was wrong, and a simple remedy for improvement based on an attractive sociological formula: more procreation for those who should breed and less for those regarded as inferior.

Eugenics sanctioned an enormous range of practices. Although eugenicists focused attention on the human genotype and the inadequacy of public health programmes that ignored heredity, they were not uniformly dismissive of social and environmental reforms. These were needed to allow the better stock to fulfil its

potential and because many believed that nurture *could* affect nature: heredity might be a limiting factor, but significant reforms were needed to fulfil hereditary potential. In almost every country in which eugenics was prominent—the United States, Britain, Japan, Germany, Russia, Brazil, and Argentina—it fitted into a comprehensive concept of social hygiene, albeit one that translated rather easily into racial hygiene (Schneider 1990; Porter 1991a; Stepan 1991; Gallagher 1999).

A third element of this phase of the development of public health was the rise of nutritional science. Although the effects of food on health had broadly been central to Western medicine throughout its history, apart from the linkage between scurvy and a lack of fresh vegetables, malnutrition and famine had remained outside public health. Remarkably, a science of nutrition that discriminated the particular effects of specific foods only began to take shape in the second half of the nineteenth century, chiefly in the new institutes of agricultural science where animal diets were being studied (Carpenter 1994). Most important was the link of several clinically distinct conditions with a deficit in trace substances in the diet. Particularly remarkable were Goldberger's association of pellagra in the American south with a too heavy reliance on maize, and the recognition of the roles of vitamin D and sunlight in the emergence of rickets. By the 1930s, public health included attention to a varied diet with adequate vitamins (Etheridge 1972; Apple 1996; Marks 2003; Kunitz 2007). Diet, like genes, loomed in the public imagination as the cause of all troubles, and a universal source of hope.

Thus, during this golden age of public health, people in the developed world learned to fear three malign entities: the invisible germs of disease, which might come through the most casual contact; the mysterious genes in their gonads; and the peculiar set of trace nutrients that their food might not contain. Their health and survival depended on all these, yet governments could control them only partially; successful control depended on their behaviour. Hence, a significant role of public health was to educate, advise, and admonish. The citizen, particularly the female citizen, was now being asked to uphold a new standard of cleanliness and to clean things that were not visibly dirty with new kinds of disinfectants. It became important to exercise new prudence in choosing a mate and controlling sexuality. A doctor was required to see whether the baby was being properly fed (Apple 1987; Hoy 1995; Tones 1998).

Ignorance heightened these hygienic demands. It was clear from tuberculin tests, for example, that exposure to tuberculosis was widespread, in some places nearly universal, but far from clear what was required for exposure to evolve into pulmonary consumption: whether it was a matter of concentrated exposure, the victim's own constitution, or the diet and environment. All seemed plausible; the advice of public health authorities (who were concerned with infected cases and with their potential for infecting others) involved every aspect of life. It was not simply a matter of not spitting, but of disinfecting eating utensils, clothes, and bedclothes; transforming relations with a spouse, family, and co-workers; and changing diet, leisure activities, and the climate of dwellings (Newsholme 1935; Dubos and Dubos 1987; Smith 1988; Barnes 1995; Roberts 2009).

Some modern historians have been surprised that these long lists of seemingly exhausting and impossible hygienic expectations, each with no guarantee of health, did not trigger widespread

resentment, victim-blaming, and excessive violations of rights (Armstrong 1983). Four factors are important: first, this was an age stunned by scientific and technical achievement and lacking for the most part a critical vocabulary for mediating expert advice. Second, it was an age of mass aspiration to middle-class standards of living, which were manifested in health, behaviour, and cleanliness. Third, all this was taking place against the backdrop of falling mortality and morbidity, and increasing domestic comfort. Fourth, these efforts were redolent with the ethos of progressive development of the community and the state (Lewis 1986).

The return of liberalism, 1970 to the present day: lifestyle, environment, and welfare

The decades following the Second World War brought a marked shift in the focus of public health and the expectations of the public. In the developed world, the infectious diseases that had so long been the chief focus of public health receded, with effective immunizations, antibiotics, or epidemiological or environmental control (Rogers 1990). With the defeat of fascism and decline of communism, liberalism re-emerged. This was symbolized in the mission statement of the World Health Organization (WHO) that health and welfare were the birthright of all (WHO 1968). It was the obligation of states to deliver that right to their populations, who now, at least in the developed world, were made up of those who saw themselves as individual free agents, diverse perhaps in culture but equal in rights. In such a situation, the conflict between the imperatives of public health and civil rights re-emerged. It remains the most formidable issue that public health faces.

The retreat of infectious disease made clearer the failure of developed nations to grapple with chronic diseases, some of which were the price of longer lifespans (Fox 1993). Some of these could be prevented by changes in behaviour: epidemiological studies in the 1950s and 1960s showed the deadly effects of good living including smoking and a rich diet (Susser 1985; Marks 1997; Porter 1999). A new set of personal disciplines emerged to control lifestyle diseases and prevent accidents—apart from exercise and shedding weight, not smoking, avoiding fats, recreational drugs and alcohol, and using condoms, one was to use seat belts and child harnesses, cope with childproof caps on medicine bottles, and accept a fluoridated water supply. These measures often met with objections because they intruded into personal liberty or on culture, or were irksome or unpleasant.

Post-war, public health concerns also shifted from individual hygiene back to the environment (Hays 1987; Gottlieb 1993). To many, heart diseases and cancers, and other serious conditions such as birth defects and lowered sperm counts, had broader structural causes and could be prevented only by comprehensive changes in the physical and social environment (Epstein 1979; McNeill 2000). Thus, part of the liberal resistance to public health impositions was the argument that a focus on disciplining lifestyles detracted from attention to grander and more serious political issues (Tesh 1987; Turshen 1987; Levins and Lopez 1999).

While this new environmentalism harked back to nineteenth-century views of public health as environmental improvement, there were greater differences. The fear of insidious invisible radiation or toxic chemicals in consumer products mirrors the terror of germs or of invisible odourless miasmas; however,

the blame was quite differently directed. The new problems of environmental public health were those in which individuals were victimized by corporate oligopolies and by the governments they influence.

Although Chadwick and his associates had warned of vested interests, such as those that perpetuated slum housing, nineteenth-century environmental health problems had a communal character that was missing from the twentieth. Everyone in a nineteenth-century town produced excrement, smoke, ash, and rubbish; the great problem was to find within the community the will and means to act collectively (Wohl 1977; Kearns 1988). Few in a twentieth-century community produced radiation or toxic chemical waste, and the reasons why nothing was done about these seemed clear. Public health had failed in its police function; an institution that had evolved to stop the selling of spoiled food by the individual grocer or restaurateur could not cope with the vast industry that sold goods whose harmful effects were less obvious and slower to appear but which might be much more widely distributed. Concern about the health effects of global climate change epitomized the problem: the scale and seriousness of the problem and attendant health problems often seem disproportionate to the heritage of environmental policing.

The growing gulf between potentially health-threatening factors and institutional responses has sometimes resulted in a fraught relationship between the people and public health. To the degree that governments were perceived as colluding with the proliferation of health-harming materials, public health institution as government departments were implicated too (Steneck 1984; Brown and Mikkelsen 1990; Edelstein 2004). Even the establishment of new departments of environmental protection to apply new expertise to environmental health problems, did not fundamentally alter the climate of distrust. Public health again became a matter for grassroots political agitation with the emergence of neo-populist Green parties, which gave prominent attention to health as part of environmental good. Public participation became increasingly important (Jasanoff 2005) as victims were not confident that the government would even recognize their disease unless a community of sufferers took it upon themselves to agitate for attention (Packard et al. 2004).

This focus on bad environmental policy even informed the response to AIDS and other infectious diseases like Ebola fever that appeared in the 1980s. Although it became clear that these diseases could be largely controlled through traditional approaches such as changes in personal behaviour and isolation or restriction of the activities of victims, it did not deflect demand for a vaccine, and investments to find a cure. These infections could be seen as diseases caused by environmental changes that allowed animal viruses to acquire secondary human hosts for whom they were highly virulent. Chief among these changes was the unwise exploitation of tropical forests by industries that put profit ahead of prudence (Garrett 1995).

Even lifestyle-related diseases could be attributed to the broader social environment. People smoked, drank, used drugs, ate too much or vastly too little, practised unsafe sex, spent hours immobilized before televisions absorbing images of violence, hit their spouses and children, or shot their co-workers or themselves because they could no longer cope. To expect disciplined personal behaviour from alienated people living in a stressful world was unrealistic, and public health institutions should recognize this.

However, critics were divided on the implications of such an analysis. Some felt the obvious response was to remake society with support structures more consistent with health behaviours it wished to promote. How absurd, for example, for a state to subsidize tobacco production while blaming its own citizens for smoking (Brandt 2006). For others, such a response sounded like an even more invidiously intrusive state. In this 'critical public health' view, the lifestyle agenda was suspicious. It was the public health agenda of an untrustworthy state, not one that its people would have chosen. It was not clear that the personal benefits of delayed or denied gratification were worth it: perhaps one should just enjoy life and rely on the miracles of modern medicine for redemption (Petersen and Lupton 1996).

This view, together with the emergence of cancers and other chronic illnesses for which there was no clear preventive strategy, including age-related debilitating conditions, raised the question of why supportive and curative medical care was not a public health concern or priority. It also highlighted the long-standing question of how far-reaching the health obligations of the liberal state to its citizens should be.

In socialist or social democratic politics, or where the legacy of medical police remained strong, there was often no clear boundary between public health and the public medical care most people demanded and received (Porter 1999). But elsewhere, the recognition that public health was bound up in the larger issue of human welfare, which in turn included the rest of medical care, was problematic. Many of the newly prominent diseases were not infectious; they could be experienced privately without disturbing community or state, hence the reactive and police rationales for public health did not apply. But they did disrupt the fulfilment of human potential, exacted great costs on productivity, increased the strains on publicly or risk-pooled funded health services for the treatment of advanced disease and their complications, and hence could justly take their place among the demands citizens could make of their governments.

In France, Germany, and Russia, public health services had emerged from, and had remained closely linked to, medical services for the poor (Labisch 1992; Ramsey 1994; Solomon 1994). In mid-nineteenth-century England, Edwin Chadwick, notwithstanding his own post as chief administrator of relief to the poor and the existence of a comprehensive national network of poor law medical officers, had deliberately severed public health (which he equated with sanitary engineering and saw as exclusively preventive) from medical care for the poor. Such medical care was second-rate, grudgingly made available because it was seen as a constitutional right. Expectations of effectiveness were low, however: it was hoped that the poor quality of public medical relief would spur the poor to pay for something better. While moderating the focus on sanitary engineering, Chadwick's English successors retained a distinction between public health medicine and social welfare, which seemed to them only marginally medical (Hamlin 1998). At the end of the nineteenth century, the Fabian socialists presented British parliament with a much expanded scheme of prevention, but which placed even greater impositions on personal and social behaviour in exchange for more guarantees from the state. The liberals, whose view prevailed, offered instead an insurance plan to pay for the medical care needed by stricken working men (Fox 1986; Eyler 1997). It was a policy acceptable to the rank and file of the medical

profession and that retained and reinforced the split between public health and clinical medicine.

Subsequent efforts to expand state responsibility for health into matters of care and cure have generally worked when medical professions have seen them as advantageous (Starr 1982; Fox 1986; Levins and Lopez 1999; Epstein 2003). However, the kinds of objections that were made to Webb's scheme still arise: however laudable prevention as a goal, ironically, as we have seen with the concerns about lifestyles and the environment, the strategies and priorities of the preventive public health of the last two centuries have not always been those most desired by the masses of people. To many it has seemed that if the state was going to discipline behaviour for its own purposes, those who suffered that imposition deserved compensation for their trouble when things still went wrong.

Such logic was clearest in compensating war veterans. It underpinned the post-war establishment of Britain's National Health Service, which would provide 'health for heroes' and sustains the Veterans Administration medical system in the United States. Thus, what some have complained of as an unrealistic demand for risk-free living, in which people demand a political right to complete freedom of action without accepting responsibility for the consequences, may be better understood as a concern about the fairness of the basic social contract of modern societies.

In many respects, the political problem of the relationship between public health institutions and the citizenry for whom they claim to act, is the greatest challenge currently facing public health in the developed world—though it is an important issue elsewhere too. In the past decade, led by WHO, there has been much interest in an integrated approach to 'social determinants of health' and in particular to the impact of real or perceived social inequalities (Cook et al. 2009; Wilkinson and Marmot 2006; Wellcome Institution 2010). But the discoveries of increasingly sophisticated epidemiology do not quickly translate into political will or effective policy. Many diseases as well as poor health more generally result from many causes operating on many levels. Accordingly, there are numerous points where defensible preventive measures might be taken. But, almost all of them are likely to intrude on what are seen as rights or interests, and questions of fairness. Epidemiology therefore requires significant supplementation from a moral and political philosophy that must be acceptable to an increasingly diverse community. Without such a foundation, public health is forced to take refuge in science that is frequently challenged; but simultaneously, it is not clear whether the professional and educational institutions of public health, or the legal, political, and administrative structures that create and maintain it, will be able to initiate and implement a satisfactory approach to how these conflicting rights are to be adjudicated.

The history and development of public health in low- and middle-income countries

Than Sein

Introduction to the history and development of public health in low- and middle-income countries

The fundamental public health actions often have to take into account or to address social determinants of health, which fall outside the domain of the health sector and also beyond the individual's action. The socioeconomic, health, and other development status of the world have been changing rapidly and radically in recent decades. Nevertheless, the majority of people in many low- and middle-income countries (LMIC), which make up about 50 per cent of the world's population, are still living in poverty with very low health status. Based on the United Nations (UN) classification of countries by per capita gross national income (GNI), countries which have per capita GNI below US \$1005 or less in 2011 are termed low-income countries (32 in total), those which have per capita GNI between US \$1006 and \$3985 are lower middle-income countries (38 in total), and those between US \$3986 and \$12,275 as upper middle-income countries (42 in total). Countries with per capita GNI above US \$12,276 are categorized as high-income countries (UN 2012).

This chapter addresses the 112 countries which have been classified as the low-, lower middle, and upper middle-income countries, collectively referred to here as LMIC. The population of LMIC (excluding that of Brazil, China, and India) is around 3 billion (which is about half of the world's population), and, thus, the advancement of health in LMIC has a major impact on the health of the world. The present chapter highlights an updated review of the history and development of public health in LMIC, covering key factors and events during the transition period from the twentieth to twenty-first century.

The first section briefly traces public health development in LMIC from the colonial period to the present day, highlighting the importance of environmental promotion, prevention and control of old scourges like smallpox, cholera, plague and yellow fever (YF), and control of vaccine-preventable diseases with ultimate aim for elimination. The epidemiological, technical, political, and financing aspects of prevention and control of selected tropical diseases are highlighted. The emphasis on control of a few priority communicable diseases has often been associated

with less active attention to many other tropical diseases and chronic non-communicable diseases (NCDs). The subsequent section describes how the strengthening of health systems including human resources and health research has helped to shape the overall health development. The next section touches upon the influence of social determinants and health inequity which have led to conceptual changes on social medicine and public health. The last section covers the globalization, prevention, and control of emerging diseases. It ends with future challenges and opportunities for health development in LMIC.

Public health development

In LMIC which were colonial territories during the eighteenth and nineteenth centuries, both public health, including prevention and control of major tropical diseases like smallpox, cholera, plague, YF, etc., and health services for patients remained underdeveloped.

The initial foundations for public health were formally laid down through the intensification of international public health actions including international health diplomacy in the mid 1800s, when the United States and European countries applied protective legislative measures through international conventions. The World Health Organization (WHO) was born in 1946, as the first truly international and inter-governmental agency, whose two main functions were to direct and coordinate international health work, and to cooperate with Member States and partners in international health development.

Environmental health promotion

From the very beginning, the promotion of environmental health including public housing, public water supply, personal hygiene, and sanitation has been recognized as a key element for national public policies, legislative actions, and personal practices for effective health and social development in LMIC. Despite legislative measures supplemented by public health education campaigns, public subsidy support, and private donations, the progress in environmental health in LMIC has not been satisfactory. According to the *World Health Statistics 2012*, the population using improved drinking-water sources¹ in LMIC had increased from 70 per cent in 1990 to 87 per cent by 2010, while the population using

improved sanitation² in the same group of countries in 2010 was still less than 50 per cent (WHO 2012a). By 2010, about 2.4 billion people around the world, mostly in Asia and Africa, were still lacking access to improved sanitation facilities, mainly due to the low priority given to the sector, inadequate financial resources, lack of sustainable water supply and sanitation services, and poor hygienic behaviours. The situation is exacerbated by inadequate provision of improved water supply and sanitation facilities in public places like wet-markets, movie theatres, schools, hospitals, health centres, and offices. Providing access to low-cost, adequate, and simple improved drinking water sources as well as improved facilities for sanitary disposal of excrement, and promoting sound hygienic behaviours amongst the general population in LMIC, are of critical importance in reducing the burden of communicable diseases (WHO/UNICEF 2012). Given the current economic growth prospects, LMIC have the challenge of getting additional financial support from external agencies, in order to achieve the Millennium Development Goal for environmental improvement.

Control of old scourges

Smallpox, cholera, plague, and yellow fever have been termed as scourges of the last centuries, since these diseases were major crippers and killers during the eighteenth and nineteenth centuries. While effective prevention and control measures are available, a substantial portion of the world's population, especially in LMIC, has not been able to gain access to these preventative measures such as effective vaccination. As a consequence, mortality and morbidity associated with these infections remain unacceptably high.

The effective control of smallpox in LMIC in the early nineteenth century was hindered by a range of factors such as impurity and variable potency of the vaccine, poor vaccination techniques, low coverage among the general population, lack of commitment by the colonial administrations, insufficient quantities of heat-stable vaccine, and lack of confidence in vaccination amongst the local populace. Consequently, several thousands of people were infected and 30–50 per cent of affected people died. Those who survived were left disfigured by ugly pox-marks and blindness (Ko Ko 2005). With the assurance of adequate supplies of effective freeze-dried, heat-stable smallpox vaccine provided free-of-cost by major vaccine producers (United States and Soviet Russia) and with ample financial support for running the vaccination programmes, the worldwide control of smallpox with an ultimate aim of eradication was launched in 1958. Through mass smallpox vaccination campaigns, several LMIC were able to control smallpox outbreaks and cut the cycle of transmission. They all reported their last smallpox cases within the next 3–4 years. Nonetheless, as recently as 1967, some LMIC in Asia and Africa, especially those with weak health infrastructure, still experienced sporadic outbreaks of smallpox that killed 2–3 million people annually. However, continued global advocacy, and the provision of technical, financial, and human resources support, led to successful containment of the disease within a decade from 1967. A combination of strategies was used such as routine and mop-up mass vaccination, coupled with intensive case-detection, contact tracing, isolation of cases, and vaccination of individuals in the vicinity who could have been exposed to the infection. The last naturally-acquired human smallpox case in the world was reported in Somalia in October 1977. There was a laboratory

accident which resulted in two human smallpox cases in the UK in 1978. By May 1980, the world was declared free from natural transmission of smallpox virus (Fenner et al. 1988). Although no further human case from natural infection by smallpox virus has been detected (zero case transmission) to date, a few vaccine-induced smallpox cases occurred in the United States, as recently as in 2010 (Centres for Disease Control and Prevention 2010). An international arrangement was made in 2011 to create an emergency stockpile of over 60 million doses of the first- and second-generation smallpox vaccines in safe and secure places, to be used for the effective control of any smallpox outbreak that might occur (WHO 2011a). The eradication of smallpox in 1980, however, stands out as the most successful public health intervention achieved globally in the twentieth century.

Cholera, one of the most devastating illnesses worldwide for many centuries due to its severity and quick and easy spread across borders, has thus been identified as a globally notifiable disease under the old version of International Health Regulations (IHR). It is still an international threat, since sporadic epidemics still occur in over 50 countries around the world (WHO 2011b). The last big-scale epidemic of cholera occurred in Haiti, in the aftermath of the massive earthquake in January 2010, which affected 230,000 people and caused more than 4500 deaths. Effective vaccines against cholera are still under development, and environmental health and good personal hygienic practices remain the only effective preventative and control measures. Properly administered rehydration therapy can also save thousands of lives who may otherwise die of dehydration and electrolyte imbalances.

Human plague, often regarded as a problem of the past or an ancient disease, resurfaced in the twenty-first century in 16 countries of Africa, Asia, and America, with around 12,500 cases of human plague (three-quarters of whom died). This clearly demonstrates the need for strengthening surveillance on rat falls (deaths of rats around human habitats) as well as human plague cases, improving preventative and control measures, and having early case finding and prompt treatment of human cases in endemic countries. All these require an effective public health and health systems infrastructure (WHO 2010a).

With the availability of an effective vaccine since 1940 together with vector control and the widespread adoption of personal protection measures, YF disease has been virtually wiped out in certain parts of Africa and Americas. As there is no effective specific treatment, immunization is the single most important means of protection against YF. However, due to inadequate health infrastructure and inadequate coverage of YF vaccination, the disease remains endemic in 34 African countries, with sporadic outbreaks occurring almost every year leading to an estimated 180,000 cases (WHO 2003). The ongoing circulation of wild YF virus, coupled with the low vaccination coverage and the presence of the vector mosquitoes around the world, means that YF will remain an important threat for international spread. Millions of lives could easily be lost, unless a substantially enhanced surveillance system and high coverage of YF vaccination in the countries at risk are sustained.

Elimination of vaccine-preventable diseases

With increasing availability and accessibility of improved vaccines for various infectious diseases which affect young children such as poliomyelitis, diphtheria, tetanus, measles, and tuberculosis, LMIC have initiated national immunization programmes, under the

aegis of the global Expanded Programme of Immunization (EPI) in mid 1970. The EPI planned to control a few vaccine-preventable diseases with the ultimate aim of eliminating or eradicating them. With support from UN agencies and other development partners, all LMIC implemented the national EPI programme, by targeting universal child immunization (UCI), i.e. fully immunizing at least 80 per cent of all children at 2 years old, with essential vaccines. In reality, the majority of LMIC took more than two decades to improve their UCI coverage to the desired level for elimination of vaccine-preventable diseases. This was mainly due to the lack of human and financial resources to effectively deliver appropriate vaccines. In 2010, 130 countries (the majority from upper and lower middle-income groups) had achieved 90 per cent coverage for three doses of diphtheria–tetanus–pertussis (DTP3), and an estimated 85 per cent of infants worldwide (compared to 74 per cent in 2000) had received at least three doses of DTP vaccine. Despite this overall improvement in vaccination coverage, routine vaccination programmes need to be further strengthened nationally, especially in countries (the majority from least developed nations) with the greatest numbers of unvaccinated children. This situation highlights the need to address issues of limited national and community resources, competing health priorities, poor health systems management, and inadequate monitoring and supervision (Centres for Disease Control and Prevention 2011). Fig. 1.3.1 shows the immunization coverage of major childhood vaccine-preventable diseases by WHO Regions in 2010 (WHO 2011c).

Except for good coverage of BCG vaccination (at over 80 per cent), the coverage of all other vaccines is under 80 per cent in countries in Africa and South East Asia. Despite these challenges, the Global EPI initiative has been considered by many public health professionals as a silent revolution in public health in the late twentieth century.

Poliomyelitis is an acute potentially paralysing vaccine-preventable disease occurring in both tropical and

temperate countries. When the initiative for Global Eradication of Poliomyelitis, within the EPI programme, was launched in 1988, many LMIC were faced with intense challenges since these countries had to improve and sustain the high coverage of routine immunization for all vaccines under the EPI programme, while improving their basic health infrastructure. At the start, the wild polio virus was circulating in more than 125 countries in five continents, disabling more than 1000 children every day. With concerted efforts, the average global coverage of polio immunization over two decades reached around 80 per cent, with Africa having the lowest coverage. Fig. 1.3.2 shows the trends for the coverage of poliomyelitis immunization (three doses) for infants by WHO regions, in 1980, and 1990 to 2009.

A campaign for national immunization day(s) (NID) was therefore launched globally in mid 1990, by assigning fixed date(s) of a year as special day(s) for polio immunization. Through NID campaigns in 2003, around 415 million children under 5 years old in the 55 LMIC were immunized with over 2.2 billion doses of oral polio vaccine. In addition, with support of the GAVI Alliance, 14 countries in Africa and Asia which had achieved the polio-free status could stop the spread in 2005 of wild polio virus imported from other countries. By the end of June 2009, infection due to indigenous wild polio virus existed in four countries only. Of the total of 440 new polio cases, ten cases were from Afghanistan, 30 from Pakistan, 89 from India, and 321 from Nigeria. A concerted effort to intensify polio eradication by interrupting transmission of wild polio viruses in all polio endemic countries was made by implementing multiple rounds of NIDs and other supplementary immunization activities, and by limiting the risk of reintroducing wild polio virus into other polio-free areas, especially neighbours. This was achieved through strong political will and support, community involvement, and national and international resources. India had reported no more internal transmission of all wild polio viruses for the whole year of 2011, and it had been removed from

Fig. 1.3.1 Vaccination coverage of major vaccine-preventable diseases by WHO Regions in 2010. Abbreviations: BCG, Bacille Calmette–Guérin; DTP3, three doses of diphtheria–tetanus–pertussis vaccine; Polio3, three doses of polio vaccine; MCV1, one dose of measles-containing vaccine; HepB3, three doses of hepatitis B vaccine; Hib3, three doses of *Haemophilus influenza* type b vaccine.

the list of polio-endemic countries in February 2012. By mid 2012, only three countries, i.e. Afghanistan and Pakistan in Asia, and Nigeria in Africa, had endemic infections with indigenous transmission of wild polio viruses. These countries had accounted for 90 per cent of all new cases of polio in 2010 and 2011. Surveillance on new polio cases and acute flaccid paralysis cases with timely and prompt response for control is very crucial in these countries (WHO 2012b). The need for this was highlighted by outbreaks due to circulating vaccine-derived polio virus in nine countries in Asia and Africa, even in 2011. While the prize of achieving polio eradication is enormous with thousands of children spared paralysis or death every year, the continued transmission of wild polio virus in a few countries is the real threat to the possibility of global eradication. Failure of global polio eradication efforts, while seemingly unthinkable, would result in the return of polio infections around the world and would constitute the most expensive public health failure in history. In May 2012, the World Health Assembly called polio eradication a programmatic emergency for global public health, especially for those countries where wild polio virus transmissions still exist (WHO 2012c). If and when the world successfully eradicates wild polio virus, this would represent a major milestone of public health success in the twenty-first century.

Immunization against measles, an easily transmitted viral infection responsible for around 10 per cent of deaths from all causes among children aged under 5 years globally, was included as part of the routine EPI programme in all LMIC since mid 1970. By 2000, 72 per cent of the world's children received at least one dose of measles vaccine (against 16 per cent in 1980). The entire American continent had eliminated the measles infection (i.e. no indigenous case for more than 12 months) by 2002. This prompted

countries from other continents to launch the global measles initiative, aimed to boost routine coverage of measles vaccination (at least a single dose) to more than 90 per cent of children under 1 year in every district of the high-burden countries. Increased emphasis was placed on laboratory-backed surveillance of new measles cases, and continuous monitoring of vaccination coverage. The number of children dying from measles had dropped worldwide from an estimated 750,000 in 2000 to 197,000 in 2007 (WHO 2009a). While it may not be possible for many LMIC to achieve measles elimination in the near future, immunization of all infants is nevertheless highly beneficial in reducing sickness, lifelong disability, and deaths at early ages.

A high coverage of immunization with tetanus toxoid (TT) to all women of childbearing age and a high coverage of DPT (diphtheria, whooping cough, and tetanus) vaccine for infants and with boosters among school children, are the simplest and most cost-effective ways to reduce tetanus infection in women and neonates, as well as deaths due to neonatal tetanus (NNT). Efforts have been made to eliminate neonatal tetanus (reducing to the level of incidence of one NNT case per 1000 live-births in all districts) since 1989. However, by the end of 2010, around ten countries of the world, all from LMIC, remained tetanus endemic.

Immunization against hepatitis B (HepB) virus, another highly prevalent infection, was introduced as part of routine EPI vaccination in LMIC since early 1990. After two decades, almost all LMIC have used both plasma-derived and recombinant HepB vaccines, achieving over 70–80 per cent coverage. If the continuous vaccine supply can be ensured and the programme is properly managed, HepB infection could be under control and even eliminated within the next one to two decades.

A potent vaccine against infection by *Haemophilus influenzae* type b, or Hib has been available since mid 1980 in high-income countries. Large-scale studies in LMIC of Africa and Latin America, and recently in Asia showed a substantial reduction in the burden of pneumonia and meningitis among infants and young children (WHO 2006a). However, latest coverage data still showed that Hib vaccine coverage in Asia and the Pacific was lower than those of other regions.

Neglected tropical diseases

Neglected tropical diseases (NTD) are a group of infectious diseases of the tropical countries that cause illness and death of thousands of people living in the tropics worldwide. Leprosy, an age-old disease, but neglected for some decades, has been put under control by accelerated efforts in introducing multi-drug therapy and a call for its elimination. Extensive coverage of treatment of all registered leprosy cases with multidrug therapy (MDT) in endemic countries was pursued in early 1990. Within a decade, several millions of registered leprosy cases were put under supervised treatment, achieving cure of the disease within a year. By 2001, 107 of 122 endemic countries were able to achieve the global target of leprosy elimination, i.e. reducing the prevalence to a level below one case per 10,000 people. Globally, the number of new leprosy cases came down from a peak of 775,000 in 2001 to 299,000 in 2005, and by 2010, only 228,500 cases. The burden of leprosy continues to decline globally as a result of collaborative efforts carried out by national leprosy programmes along with continued support from both national and international partners. By the end of 2011, around 120 endemic countries achieved the global elimination target (WHO 2011d). If the current trend in disease reduction is well sustained with full support from the Global Alliance, the incidence and total burden of leprosy could be further reduced in all endemic countries in the near future. Leprosy elimination might become another public health landmark of the twenty-first century.

Visceral leishmaniasis or kala-azar, another NTD, has been put under control by using an oral medication, miltefosine. A new candidate vaccine is under trial in India in 2012. Until newer medicines and appropriate vaccine(s) are available at affordable prices, and made accessible to the mass population in the endemic countries, the misery and suffering of thousands of people from visceral leishmaniasis would continue.

Onchocerciasis also known as river blindness, another parasitic infection, is still endemic in 37 countries in Africa and Latin America. A million people are visually impaired and over 300,000 people are blind as a consequence of this disease. The Global Onchocerciasis Control Programme that was launched in 1974 tried to reduce severe pathological manifestations through community-based mass management with a microfilarial drug (ivermectin), combined with vector control. Although the disease is a preventable cause of blindness and its elimination goal is achievable, there is a great deal of work to be done in endemic countries (Diawara et al. 2009).

Dracunculiasis is a parasitic, vector-borne guinea worm infestation. Many endemic countries in Asia and Africa were able to achieve the global eradication target, set in 2004, by reducing the annual incidence from 3.5 million in 1986 to fewer than 1100 cases in 2011, with over 90 per cent of them in Sudan (WHO 2011e). If concerted efforts continued, eradication of dracunculiasis could

be achieved in the near future without any use of vaccine and medicine.

Trachoma is a chronic repeated infection of the eyes by the bacterium *Chlamydia trachomatis*. It affects poor people and children living in the tropical countries of Asia and Africa, where unhygienic personal practices still prevail and people are not able to access adequate water supply. Surgical intervention, the grey-line split and splint technology to correct early cases of entropion and trichiasis of affected eyes, has saved millions of people from blindness (Wilfred 1979). Mass treatment with simple antibiotic (tetracycline) eye-ointment application daily for 6 months for both eyes, supplemented with field surgical treatment, and improvement of personal hygiene and sanitation, were effective strategies to reduce infection rate as well as cure the disease (Tun and Ko Ko 2007). Cost effectiveness of these multiple integrated strategies carried out in Myanmar has been documented (Evans et al. 1996). Many endemic countries implemented the WHO-advocated SAFE strategy (surgery, antibiotics, facial cleaning and environmental improvement) under the national integrated trachoma control programme, within the Vision 2020 strategy aiming for ultimate elimination of the disease.

The global eradication effort for yaws, another disabling NTD, through vaccination, has been launched in many countries around the world for the last five decades. However, sporadic epidemics and scattered foci of infection still persist in some parts of Latin America, the Pacific, and South and South East Asia. Extensive surveillance and case finding, use of newer antibiotics, and follow-up of treated cases and contacts, became important strategies for eradication of yaws from the remaining endemic countries.

Lymphatic filariasis (LF) is also a disabling NTD caused by blood-borne infection by microscopic thread-like parasitic worms—*microfilariae*. The global programme to eliminate LF was launched in 2000 and more than 3.4 billion doses of anti-microfilarial medicines were delivered to a targeted population of 897 million people. Vector control measures combined with mass drug administration can interrupt disease transmission and reduce the parasitic levels. Despite decades of such efforts, LF continues to be highly prevalent in many countries mainly in Asia, the Pacific, and Africa, with an estimated 120 million infected people in 72 countries in 2010 (WHO 2011f).

Chronic non-communicable diseases

While infectious diseases continue to be major public health problems in LMIC, chronic NCDs have become increasingly prevalent and important as a public health challenge. Recent estimates of the global burden of NCDs and their risk factors showed that over 36 million people died (almost 63 per cent of all deaths) in 2008, principally from cardiovascular diseases, diabetes, cancer, and chronic obstructive respiratory diseases. More than 60 per cent of the global burden of cardiovascular diseases is in LMIC. Many large-scale, well-designed clinical trials had shown that lowering the common risk factors like tobacco and alcohol use or unhealthy diets can reduce morbidity and death from NCDs. The dual approach of screening and mitigating risk factors in relatively high-risk groups and of promoting population-wide preventative activities to reduce health risks such as tobacco and alcohol use with policy and legislative measures is an appropriate strategy for LMIC.

Diabetes mellitus, either type 1 (insulin dependent) or type 2 (non-insulin dependent), has affected around 200 million people of above 20 years of age worldwide. Many patients with type 1 diabetes in LMIC still do not have adequate access to insulin. The number of patients with diabetes may increase to 370 million by 2030, if proper prevention and control strategies are not in place. With early screening and diagnosis, followed by effective management with diet, exercise, and essential medicines, diabetes and its complications can be potentially controlled.

Cancer is a well-known NCD and a leading cause of death worldwide with more than 70 per cent of all cancer deaths occurring in LMIC. Liver cancer affects approximately 5.5 million people, predominantly caused by viral hepatitis. Stomach cancer, caused by *Helicobacter pylori* infection, could be easily prevented by early prevention and control of infection with appropriate medicines. Early detection with proper screening and improved treatment of breast cancer has reduced mortality by 45 per cent in women above 50 years of age. Cancer of the uterine cervix, which is prevalent among women of childbearing age, is mainly due to chronic infection with sexually-transmitted human papilloma virus (HPV). Pap smear screening and early treatment has significantly reduced mortality from cervical cancer. Some high- and upper middle-income countries have introduced vaccination against HPV infection, with a view to reducing cervical cancer (WHO 2009b).

Strengthening health systems

For effective disease control, viable and efficient health systems are necessary. Many governments of LMIC at their independence tried to establish their public health facilities based on the model of their colonial masters. In general, the health systems in most countries were publicly funded, except in some African countries where basic healthcare was reliant on health facilities and staff supported by local and international nongovernmental organizations (NGOs). A number of medical schools and paramedical training institutes, public health training and research institutions, and health centres were established with technical assistance from the colonial rulers.

Up to the 1960s, many LMIC had weak health infrastructure for maternal and child health (MCH) care, despite the high mortality and morbidity from maternal and childhood diseases. Immunization coverage was very low and essential MCH care relied on poorly trained nurse-aids, midwives, or nurse-midwives at hospitals and hospital-based clinics, located mostly in urban areas. Even basic maternal and essential obstetric care services were not available. After a few decades, it was realized that the vertical approach of opening MCH centres and deploying MCH workers alone did not achieve the purpose of expanding MCH care. Various strategies were thus adopted to integrate and expand MCH services as part of essential healthcare packages. During 1960–1970, many LMIC started adopting comprehensive population policies, and family planning services as part of MCH care, to address both demographic challenges and maternal health problems. Even though simple and effective family planning techniques were available and within reach, only a fraction of women in LMIC could have access to these services.

Another critical challenge is making essential medicines available for needy patients. As many newer food supplements,

medicines, and vaccines become available, the control of substandard, spurious, falsely-labelled, falsified, or counterfeit medical products must be closely monitored. LMIC have to continually strengthen their food and drug regulatory agencies to ensure effective implementation of their national policies. With the expansion of the private sector and health insurance, ensuring access to, and in particular affordability of, essential medicines and vaccines become more vital.

Health systems based on modern allopathic medicine intended to benefit the whole population barely existed a century ago in many LMIC. To date, healthcare provision in LMIC is by the publicly-financed health systems in conjunction with private healthcare providers, supported by NGOs. Development of infrastructure for public health, mainly for communicable disease prevention and control, was usually done as part of vertical campaign programmes. There are glaring contrasts between high-income countries and LMIC as well as among LMIC themselves in achieving a higher health status. The average life expectancy at birth in 1990, in low-income countries was around 52 years and that of lower- middle-income countries was 63 years, while the upper middle- and high-income countries range from 68 to 76 years, as estimated by WHO (WHO 2012a). Many low-income countries still have child mortality rates of above 100 per 1000 live births. During the 1980s and 1990s, many LMIC adopted the health-for-all (HFA) and primary healthcare (PHC) principles and approaches to restructuring their health systems, and formulated new health policies, strategies, and programmes on this basis (WHO 1998).

While some countries concentrated on vertical campaigns for expanding personal healthcare interventions like MCH, family planning, growth monitoring, breastfeeding and immunization, other countries tried to implement comprehensive health programmes, including health legislative and health finance reforms. This is important since lack of communication and a full understanding of the fundamental values, principles and policies of PHC and HFA applicable to national health development had resulted in limitations to access to essential healthcare. Also, there was inadequate coordination and collaboration between specific health intervention initiatives like immunization or specific disease campaigns, and the development of basic health systems infrastructure. This resulted in inadequate involvement of communities in their health development efforts, and also to the slow pace of integrating vertical disease control campaigns into the basic health services. It was compounded by weak planning and management of health development, especially at the operational levels at districts and below, and the imbalance and inappropriateness of some human resources for health (WHO 2008a).

Some health development programmes in LMIC showed that the conventional approach of merely expanding basic health services was inadequate, as the public sector could not bear the cost of expansion of basic healthcare services to the entire population, in the face of existing resource constraints. Thus, many countries sought partnerships with private healthcare providers, worked with community-based civil society organizations, and deployed a large number of community-level health volunteers, who were trained for short periods to serve as a third layer of human resources for health (Sein 2006). The increasing use of volunteers in health development proved successful for expanding essential healthcare coverage in many countries. With the involvement of

private healthcare providers and community-based health volunteers, many essential public health interventions were enhanced especially in disease prevention and control including epidemic control and immunization, health promotion, maternal and child healthcare, information gathering and surveillance, treatment of minor ailments and environmental health promotion. A series of reforms in health systems such as improving the content of essential packages for health and the way these were financed were undertaken in many LMIC. The global trend in health systems development nowadays is towards the increasing role of both the for-profit and non-profit private sector.

Health planning and financing

The centrally directed planning framework using country health planning (CHP) or national planning process for health sector development, supported by WHO and UN agencies during 1970–1990, had moved many LMIC to a higher level of health attainment. It was highly successful when the health development projects based on selective healthcare interventions like immunization, malaria, or leprosy control, or selective maternal and child care, family planning, and growth monitoring were promoted on the national scale through centrally controlled, externally funded programmes. From mid 1990, external donors moved from planning multiple health development projects to an integrated sectoral planning of comprehensive health development programmes.

Around 2005, the UN introduced the principle of ‘Delivering as One (DaO)’, basically covering four areas: ‘one leader, one budget, one programme, and one office’, and later the Multi-donor Trust Fund (MDTF) mechanism to coordinate development resources and get more partners to support a single national strategy in selected LMIC (United Nations Development Group 2010). A group of development partners who share a common interest in improving health services and health outcomes for LMIC had launched, in 2007, another global initiative called IHP+ (International Health Partnership plus related initiatives). An inter-agency working group of IHP+ had developed a joint assessment tool for national health plans and strategies (JANs), and associated guidelines. In 2010, the JANs tool was applied in several LMIC as part of the national health policy development and planning process (IHP+ 2011). The national health planning processes cover now a comprehensive, balanced, and evidence-based assessment of the country’s health and health system challenges. Many LMIC tried to strengthen their institutional capacity to harmonize and align donor programmes with their national policies, strategies, priorities, and plans (WHO 2011g).

The LMIC, while struggling to improve their health systems, increasingly realized the value of developing their own health systems to provide healthcare to all people, while financially protecting them in the fairest way possible. The key challenge of health financing reform, particularly the collection of revenue and pooling and use of financial resources, is to find a good balance between ensuring that the cost of care is affordable and fair for patients, while providing appropriate incentives to healthcare providers to motivate them to improve the health of the people by improving the responsiveness of care delivery. This is in keeping with the ideal for universal coverage, which means equity of access to key promotive, preventive, curative, and rehabilitative health interventions for all, at an affordable cost.

While high-income countries continued to increase public spending on health in response to growing expectations, LMIC were struggling with major problems in managing and financing their health systems. Total health expenditure as a proportion of GDP ranged from 1.9 per cent to 6 per cent in LMIC, while high-income countries spent more than 11 per cent. Per capita government expenditure on health varies from around US \$30 in low-income, US \$90 in lower middle-income, US \$500 in upper middle-income, and more than US \$2600 in high-income countries.³ The relatively low public investment in health in LMIC has led to higher direct costs for healthcare in the form of out-of-pocket expenses for patients. In some LMIC, the local community organizes and manages their own community-based financing for healthcare, with government subsidies or technical support. While the coverage of social health insurance is high among LMIC in South and Central America, it is very low or almost non-existent in many LMIC of Asia and Africa. Where such social health insurance schemes are available, they usually cover formally employed workers as part of nation-wide social welfare schemes.

The degree of dependence on external resources for health as a percentage of the total health expenditure varied from country to country in 2009, ranging from 2–20 per cent for most LMIC in South- and South East Asia (WHO 2012a). Similarly, many LMIC in Africa had a range of 20–60 per cent, the highest being 80 per cent in Malawi. It is generally perceived that excessive dependence on external financial sources makes a country’s health system vulnerable. External aid for health, especially through large international health partnerships, can create imbalances in the overall allocation of health resources and loss of a country’s autonomy in making health decisions.

In addition to the support to health sector development by bilateral aid/grant programmes and multilateral financial institutions, there is an increasing investment in health by the national and international civil societies, and multinational pharmaceutical corporations through their foundations. The recent entry of private foundations set up by global entrepreneurs and private philanthropists in the health and social sectors, is an important trend with multibillion dollar contributions in specified funds and programmes for health development. The most recent study done by the Institute for Health Metrics and Evaluation (IHME), in its Financing Global Health Report 2011, stated that the development assistance in health (DAH) which is reaching US \$27.73 billion, has more than doubled in size between 2001 and 2009 (IHME 2011). While the DAH is usually aligned with the health priorities of LMIC, some countries with high burden of diseases have been missed out for various reasons, mainly political ones. Similarly, the inputs from DAH may have benefited programmes which primarily target specific communicable diseases such as HIV/AIDS, tuberculosis, and malaria that may affect only a minority of people in the developing countries (see Chapter 11.12 for further discussion of these issues). The proliferation of bilateral and multilateral donors, multiple global initiatives, and international NGOs also generates the potential for weakening health systems, rather than strengthening them, allowing countries to avoid issues like long-term sustainability.

Human resources for health

One key factor for success in implementing healthcare, both for public health and health system development, is having a

critical mass of competent human resources for health. As human resources consume as much as 60–70 per cent of the public health expenditure, they need to be fully developed and optimally utilized. The *World Health Report 2006* had provided a global analysis and identified effective strategies to strengthen the development of appropriate human resources for health (WHO 2006b). Despite concerted efforts to resolve imbalances and inequitable distribution, many LMIC are still confronted with basic human resources policy issues, such as the need for clear national policies on the development of an appropriate health workforce, inadequate norms and standards for health professionals resulting in inappropriate mix, inadequate mechanisms for exchange of information and insufficient standards for health professionals' education and training, and absence of quality control mechanisms for health professionals' practices. The development of human resources for health is crucial for improving health services coverage and for scaling up public health interventions. Major reasons for the health workforce shortage, while varying greatly among LMIC, include inadequate numbers due to underinvestment in basic undergraduate and graduate education and training; loss of existing workforce due to emigration to other countries; mismanagement and coordination (career structure and staff supervision); and inefficient planning.

Some of the impediments to the development of a relevant and adequately sized public health workforce are lack of incentives and career structure for public health professionals, public health training being seen as an extension of the biomedical model of clinical training, and the inclusion of many training courses and core curriculum which are either obsolete or irrelevant to the public health needs of the countries. Several networks, both formal and informal, among public health education institutions in Asia and Africa have been established to collaborate and support exchange programmes for faculty members and students, sharing of curriculum and training materials, and organizing joint research studies. The shortage of nurses and midwives in LMIC especially in Asia and Africa has been a chronic human resource issue for decades, and many countries have attempted to address this through expansion of nurse training institutions.

Health research development

While science and technology research and application have advanced rapidly in high-income countries, they have remained rudimentary in LMIC. While LMIC have to rely on the results of research and development on pharmaceuticals and vaccines from high-income countries, in practice, many breakthroughs have been contributed to by the experiences gained and the studies carried out in LMIC. In many LMIC, there are very few health research institutions and poor career prospects for researchers. Development of health research, both in biomedical and public health sciences, has been initiated in recent decades in LMIC, with respect to prevention and control of tropical diseases. Joint collaborative studies between LMIC, especially upper middle-income countries and high-income countries are carried out for development and use of medicines and vaccines for infectious diseases, promotion of human health and reproduction specifically on contraception and other fertility control measures, strengthening of health systems, promotion and protection of environmental health, and control of NCDs, and development of essential healthcare technologies. Considerable progress has been made in

capability strengthening for promoting health systems research, which has further paved the way for developing effective national health research systems. In recent years, the development of health research has been promoted through international exchanges of experience and expertise amongst the networks such as INCLEN Trust, Asia-Pacific Health Research System Network, and African Health Research System Network. A major issue faced by LMIC today is that while scientific advances and technological development of the high-income countries provide them with vast opportunities for their overall economic development, large numbers of people in LMIC are still suffering from neglected tropical diseases and undernutrition for which prevention or control interventions are already available (WHO 2010b).

Social determinants of health

The majority of LMIC are particularly susceptible to the negative impact of socially determined health inequities due to exposure to health risks, social exclusion, and other broader determinants associated with health risks including living conditions, work environment, unsafe sex, and changing consumption patterns of food, water, and information. After WHO released the report of the Commission on Social Determinants of Health in 2008 (WHO 2008b), LMIC considered the need to build up their national capacities to address advocacy, intersectoral action, evidence gathering of health inequity, and to address social determinants across sectors. They started establishing national mechanisms to coordinate and manage inter-sectoral actions for health and to bring into the mainstream consideration of social determinants of health, especially health inequities.

Tobacco is one of the common risk factors for many NCDs. Tobacco-related illnesses and deaths increased globally during the past decades with four million deaths every year, and if no proper control measures are instituted, the death toll may go up to 10 million. In South- and South East Asia, increasing use of the combination of betel-nut and tobacco as betel-quinid has become a major issue, since it causes oral, laryngeal, and gastrointestinal cancer. After adoption in May 2003 of the WHO Framework Convention on Tobacco Control (WHO FCTC), LMIC have adopted or amended their tobacco control legislation. Several countries now have comprehensive national tobacco control legislation conforming to the provisions of the Convention (WHO 2011h).

Worldwide consumption of alcohol in 2008 was equivalent to 6 litres of pure alcohol consumed per person aged 15 or older, with a large portion of this—28.6 per cent or 1.76 litres per person—being homemade, illegally produced or sold outside normal government controls (WHO 2011i). Harmful use of alcohol is a major factor contributing to premature deaths and avoidable disease worldwide. A wide range of policy options and interventions for reducing public health problems caused by harmful use of alcohol was advocated for all countries (WHO 2010c).

Preventing injuries

Injuries, being caused intentionally and non-intentionally, have emerged as a major public health problem in the twenty-first century. The rapidly rising number of motor vehicles (48 per cent of the world's vehicles are registered in LMIC), and motorcycles (adding more than a million a day on the roads) has led to an equally rapid increase in traffic-related injuries and deaths. LMIC

have a higher road-traffic related death rate of over 20 per 100,000 population, and accounted for over 90 per cent of the world's fatalities. Introduction and upgrading of safe public transport, improvement of road signs and pedestrian-crossings, compliance with traffic legislation like wearing helmets and seat-belts, and avoiding speeding and drink-driving, are important measures for reducing road-traffic injuries (WHO 2009c).

Social medicine and public health

The initial idea of social medicine or the social dimensions of public health had emerged in the early twentieth century. The concept of social medicine was developed as a new public health discipline in the late 1940s. At that time, leaders of both clinical medicine and public health questioned the perceived polarization of curative medicine and preventive medicine which included epidemiology and social medicine. The situation was exacerbated by continued specialization and the lack of cross-disciplinary interaction (Ko Ko 2011). However, the social and behavioural aspects that influenced illness and well-being are recognized and revisited in later decades, and many social and personal behavioural interventions are introduced as part of health promotion and disease prevention. Many universities and medical schools converted their departments, faculties, or schools of hygiene and public health into those of preventive and social medicine during the period 1960–1970. Instead of integrating curative and preventive medicine in the teaching of social medicine, educational institutions equated public health and hygiene with preventive and social medicine, and conventional public health teaching still has a primary focus on prevention and control of infectious diseases and hygiene. National health planners and public health specialists today need to have a better understanding about the integration of clinical medicine within its social context, and also to take into account political needs and demands of the community, widening gaps between personal and community health needs with available resources, and rising pressure of societal factors on healthcare. The general population is now becoming increasingly aware of the social and economic determinants impacting health. As a result, national debates on the linkages of health with social, environmental, economic, and political factors have started and there are more discussions at the global level to give a wider political and social dimension to international public health. Policymakers are increasingly concerned about finding equitable, realistic, and sustainable approaches to addressing social determinants of health with a view to improving health.

The history of public health development has shown the need for increasing cooperation between high-income countries and LMIC, in order to promote the health of the citizens of the world. Over the last 50 years, many international, intergovernmental, bilateral, and multilateral development agencies and organizations, as well as alliances have emerged out of necessity to deal with international developmental issues both in policy and programme terms. LMIC need to work in close collaboration with all development partners by focusing the global efforts to build healthy populations and communities by addressing the excess burden of sickness and suffering resulting from both communicable and non-communicable diseases especially in poor and marginalized populations. Partnerships could be established to sustain and support health system development so that equitable health outcomes are achieved and the needs of the people are met. More recently,

debates have intensified around global public health development and global governance of health (Dodgson et al. 2002; Kickbusch and Gleicher 2012).

Whither the new public health

In this century, many LMIC have moved from narrow, specific disease control interventions (vertical campaigns), to a wider perspective of integrated and comprehensive multi-sectoral interventions for health development. The approach of public health measures under full responsibility of the government has been supplemented with services provided by an increasing number of NGOs, foundations, and private sector agencies both at local and global levels. In addition to external financing and technical support by traditional international agencies like WHO and UN, bilateral aid agencies from high-income countries like the United States, United Kingdom, Australia, Japan or the Netherlands, and multilateral financial institutions such as the World Bank and Regional Development Banks, there are myriad international foundations and financing groups such as the GAVI Alliance and the Global Fund, as well as private foundations like the B&M Gates Foundation, that have transformed international health support and governance.

Globalization of public health

The UN launched the Joint United Nations Programme on HIV/AIDS (UNAIDS) in January 1996, with the UN-wide mission to lead, strengthen, and support an expanded response to HIV/AIDS. Another UN initiative was the organization of the UN Millennium Summit attended by 189 heads of states in 2000, where the UN Millennium Development Goals (UN MDG), of which the majority related to health, were adopted. The UN MDG targets for 2015 represented the world's commitment to deal with global poverty and health in several dimensions, with a global partnership that called for country-led strategies and support from developed countries in the areas of trade, official development assistance, debt sustainability, and access to medicine and technologies. The UN MDG became the aspirational goals for all countries, including LMIC, in reducing poverty and improving overall development, particularly health (UN 2011).

Analyses of the impact of rapid globalization on public health are available in much of the health and development literature (Drager and Beaglehole 2001) (see Chapter 1.5 on globalization in detail). Global trade, finance, information and people flows, governance, and security can all contribute to improving the health of people everywhere. The threats to and opportunities in public health, including cross-country control of infectious diseases and international governance, have been analysed extensively within the context of globalization (UN 2003; Fidler 2004). An updated version of the IHR, issued in 2008, is a guide for all countries to prevent, protect against, control, and provide a public health response to the international spread of a disease or diseases, in various ways that are commensurate with and restricted to public health risks, and that avoid unnecessary interference with international traffic and trade (WHO 2008c). There is a strong need for global collaboration to combat diseases of public health importance that are a significant threat to human health globally.

While many old scourges like tuberculosis, malaria, plague, cholera, and leprosy remain endemic or are re-emerging in some

LMIC, a few emerging infectious diseases of epidemic potential present a constant threat. These diseases include acquired immune deficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infection, Ebola and other haemorrhagic diseases, severe acute respiratory syndrome (SARS), and avian influenza. A few old tropical diseases like cholera, dengue, and YF are also emerging in new geographical areas (see Chapter 8.17 on emerging and re-emerging infections in detail).

Healthy ageing

Many LMIC, which are experiencing an expansion of the proportion of people above 60 years of age, have started paying attention to the health of the elderly. These have focused on creating closer linkages between social welfare and health, providing care at home and in the community, promoting traditional family ties, optimizing the use of existing healthcare delivery systems, and setting up old-age homes. However, access to essential healthcare for the elderly is inadequate. Knowledge among basic health workers on specific needs of the elderly is also minimal. A few countries have organized research studies related to epidemiology, demography, and determinants of healthy ageing. Some countries have formulated comprehensive intersectoral national policies on ageing and health. The economic, social, and health status of the fast-growing elderly population in LMIC poses a great challenge to all sectors. The major difficulties in developing appropriate healthcare for the elderly include the lack of reliable data for programme planning, a virtual absence of national policies and strategies for the care and social welfare of the elderly, and inadequate infrastructure to cope with their rapidly increasing health needs.

Looking ahead

Many LMIC had undertaken a series of new, third-generation, health reforms, such as improving the content of essential packages for health and the way these were financed. Many models of health financing either at national or local levels were developed, including reforms in expanding social health insurance. Another global trend in health development is the increasing role of the private sector, both for-profit and non-profit. Fewer non-profit agencies were involved in public health development and medical care to under-served populations. It is not a simple solution of privatization, but a balanced mix of both public and private healthcare, that can fit within the existing socioeconomic, political, and health situation of the country, and the extent the national health plans would ensure that wider reforms would address the gaps in healthcare and create a pro-poor health system.

The linkages between social and economic development and health improvement were recognized by many LMIC in 1980–1990. There was a dramatic change in international public health development, especially global health governance and international cooperation. The centrality of health to human development is embedded in a wide range of national and international agreements and affirmed in action by a wide-ranging set of stakeholders. A multiplicity of new actors in national and international health had redefined the boundaries of health sector. Groups of individuals, united to a particular cause such as patient groups or civil society both at national and international levels, have become major players for policy and programme development in public health, by creating powerful lobbies and raising public awareness. Growing numbers and increasing involvement of NGOs in the

direct delivery of healthcare had complemented the efforts of the publicly provided health systems. They have become influential players in policy development and decision-making in socioeconomic and health-related issues in many LMIC.

A new paradigm in health development in many LMIC, which have to rely heavily on external aid for health in earlier years and even now, has led to a complex relationship among traditional and new players in international health and health-related development, for guiding appropriate and effective planning and use for resources, and the need for delineation and harmonization of responsibilities. There are, however, a few concerns that the multiple international partnerships might widen the gaps by increasing fragmentation of international cooperation in health, overwhelming the national capacity to implement, distorting national priorities, diverting scarce human resources, and also marginalizing the UN system's agencies.

Conclusion

Health is a cause rather than an effect of economic development. The history of public health development in LMIC shows that important breakthroughs in public health interventions have led to great improvements in economic development. Health actually determines economic productivity and prosperity, and physical and emotional well-being of the people. The population afflicted with a high infant mortality rate usually lacks the secure knowledge of its children's longevity, witnesses higher rates of fertility, and experiences the quality–quantity trade-off in child rearing. The efforts of national and international communities should be aimed at promoting healthy living, reducing the double burden of disease, and making essential healthcare accessible to all. Ever since the health-for-all movement was initiated over three decades ago, health, equity, and social justice remain the main themes of social and health policy. It is essential for all public health professionals to sustain these values especially those in LMIC and the international community.

Notes

1. Improved drinking-water sources are those places where drinking-water is taken from: (1) piped water into dwelling, yard, or plot; (2) public tap or standpipe; (3) tube-well or bore-hole well; (4) protected spring; (5) protected dug well; and (6) rain-water collection (source: WHO/UNICEF 2012).
2. Improved sanitation means use of: (1) flush or pour-flush to piped sewerage system, septic tank or pit-latrline; (2) ventilated improved pit (VIP) latrine; (3) pit latrine with slab; and (4) composting toilet (source: WHO/UNICEF 2012).
3. See details in Table 7, Annexure, *World Health Statistics 2012* (WHO 2012a).

Development of public health in economic transition: the middle-income countries

Kai Hong Phua, Mui-Teng Yap,
Sara U. Schwanke Khilji, and Hin-Peng Lee

Definitions of middle-income countries and emerging economies

The World Bank classifies economies according to gross national income (GNI) per capita, calculated using the World Bank Atlas method. The cut-off points are updated every year using purchasing power parities (PPP) at current international dollars. For 2011, the groups are: low income, \$1025 or less; lower-middle income, \$1026–4035; upper-middle income, \$4036–12,475; and high income, \$12,476 or more. The World Bank changed its terminology from the gross national product, or GNP, in previous publications to the GNI (World Bank 2012b). However, the definitions and groupings of ‘transition economies’ and ‘emerging economies’ in the literature have so far been hazy. The most comprehensive discussion on the terminology is by the *Centre d’Etudes Prospectives et d’Informations Internationales* (CEPII):

The term ‘emerging economies’ corresponds to various and often blurred groupings. Sometimes it is used in relation to the four ‘BRICs’ (Brazil, Russia, India and China) or a group of ‘fast growing economies’, while on other occasions, it refers to all developing countries. (Gaulier, et al. 2009)

The term ‘emerging economies’ implies not only a rapid growth of gross domestic product (GDP) per capita or an increasing presence in world markets, but also entails several important ingredients of political economy. These countries have pursued a process of economic liberalization, promoted market orientation, and opened up to international flows of goods, services, and capital and this process has been associated with the building up of institutions and strong state regulation (Gaulier et al. 2009). Various classifications of ‘emerging economies’ include the countries which: (1) have a level of income below the threshold set by the World Bank (US \$11,100 in 2006), and (2) have been able to increase their share in world markets of manufactured goods or services by at least 0.05 per cent points between 1995 and 2005. This group includes Brazil, India, Indonesia, China, South Africa, and Mexico. Similarly, the Organisation for Economic Co-operation and Development (OECD) describes Brazil, Russia, India, Indonesia, China, and South Africa, together known as the BRIICS, as the six largest

non-OECD economies rapidly integrated into world markets during the past two decades (OECD 2009).

Tables 1.4.1–1.4.3, illustrate the rapidly rising trends in GNI per capita (in PPP at current international dollars) and corresponding improvements in the Human Development Index (HDI). The HDI is a composite index combining indicators of life expectancy at birth, educational attainment (mean years of schooling and expected years of schooling), and the gross national income per capita (PPP), to provide relative rankings among all countries. Despite the improving socioeconomic conditions, there are still vast inequalities in all middle-income countries, as reflected in the Gini Index and remaining high levels of poverty. The definition of middle-income countries is increasingly associated with the group of countries somewhere between the rich and poor countries, usually undergoing transition with their emerging economies.

Economic and health transitions in middle-income countries

The relationships between public health and rapid economic development can be illustrated by examples from the fastest emerging economies in East Asia in the past decades. The growth momentum was first propelled by the four ‘tiger’ economies of Hong Kong, Republic of Korea, Singapore, and Taiwan, which opened up their economies for export-led growth in the 1980s. Meanwhile, the opening up of the economies of China and India, countries which account for nearly one-third of the world’s population, changed the dynamics of the regional and global economies. The average rate of economic growth among emerging countries in Asia at 7.5 per cent per annum during 1988–2005 was more than twice that of global economic growth over this period.

Income and health transition

The relationships between health and economic development can be examined by the correlations between national income and general health indicators. The relationship between per capita income and life expectancy among countries is non-linear. At low levels of income and development, there are discernible improvements

Table 1.4.1 Key macroeconomic indicators in middle-income countries

Country	GDP per capita PPP (int \$) (2010)	Annual GDP growth % (2010)	GNI per capita PPP (int \$) (2010)
Brazil	11,210.4	7.49	11,000
China	7598.8	10.40	7640
India	3425.4	8.81	3400
Indonesia	4325.3	6.10	4200
Jordan	5749.2	3.11	5800
Malaysia	14,730.9	7.19	14,220
Mexico	14,563.9	5.52	14,400
Russia	19,891.4	4.03	19,240
South Africa	10,565.2	2.85	10,360
Thailand	8553.8	7.81	8190
Tunisia	9549.8	3.70	9060

Note: GNI per capita of upper-middle-income group aggregate is 9971.85 (PPP int \$).

in health with increases in income with a strong positive correlation up to a per capita income level of around US \$4000 (current PPP terms). Beyond this threshold, the relationship becomes much weaker with rising income level but still remains positive. Similar to life expectancy, the relationship between income and infant mortality rate (IMR) is also non-linear. IMR declines faster with even small improvements in per capita income level at lower levels of development, but this correlation also becomes lower after the threshold level of around US \$4000 (current PPP terms) is reached. Empirical econometric studies of global or country-specific data indicate a positive relationship between health and economic

growth. For example, a study in 2001 (Bhargava et al. 2001) shows strong correlations between average survival rate and economic growth. Conversely, there is also a positive impact of overall health conditions on economic growth, as shown in another study in 2004 (Jamison et al. 2004) that health improvements are correlated to a 0.2 per cent gain in annual growth rate of health expenditure.

Income and demographic transition

The demographic transition in middle-income economies is producing large changes in age structure that impact on economic growth and standards of living. For countries that are in the early stages of the transition, high fertility and declining infant and child mortality have led to a bulge in the population at younger ages. The middle range of the transition is marked by an increase in the share of the population at the working ages, as large cohorts of children reach adulthood and as the relative number of children is reduced by fertility decline. Towards the end of the transition, the share of the older population increases dramatically. This is a consequence of both the reductions in mortality rates, as well as low fertility rates.

Since the end of the Second World War, many emerging economies have undergone an unprecedented transition in the demographic patterns, from high fertility and high mortality to low fertility and low mortality. As the emerging countries experience positive economic growth, there is a corresponding demographic change in the distribution of population due to a reduction in fertility rate. This situation has come to be known as the 'demographic dividend'. The decrease in dependency due to the reduction in births could free up resources in the country for other investments leading to economic growth.

This is enhanced by a greater proportion of the adult, economically productive, population supporting the dependent population. This 'demographic bonus' where there is a higher proportion of working population groups with less economically dependent children and the elderly, can enable faster economic development. This phenomenon has been observed in many of the fastest growing emerging economies, creating the 'East Asian miracle' in Hong Kong, South Korea, Taiwan, and Singapore, which became newly industrialized economies in the recent past, and that of Thailand, Malaysia, Indonesia, and the Philippines currently. From 1975 to 2000, there has been a dramatic decrease in the dependency ratio in the region from 78 to 56 per cent (Asian Development Bank, 2011). The dependency ratio is projected to decrease further in Asia up to 46 per cent in 2025 as fertility rates continue to decline.

However, the 'demographic dividend' is not indefinite and newer public health issues will surface as the population ages. This will become one of the biggest challenges of the more developed middle-income countries where this window of opportunity might soon close. The economically active adult population will eventually mature into the elderly population 65 years and above, who will also have longer life expectancies, hence increasing the old-age dependency ratio. This situation will become more pronounced in middle-income countries with low fertility rates which result in a smaller number of the younger age group who will eventually replace the adult population engaged in productive employment.

Economic transition and global trade integration

With regard to transition economies, the International Monetary Fund has described the ingredients of the transition process to

Table 1.4.3 Indicators of income inequality and poverty in middle-income countries

Country	GINI index (%)	Income share held by lowest 20%	Poverty gap at \$2 a day (PPP) (%)	Poverty head count ratio at \$2 a day (PPP) (% population)	Poverty head count ratio at national poverty line (% population)
Brazil	54.69 ^c	2.85 ^c	5.4 ^c	10.82 ^c	21.4 ^c

Notes: ^a2005 data, ^b2008 data, ^c2009 data, ^d2010 data, ^e2011 data, ^f2006 data.

GINI index indicates inequality of income, with 'zero' expressing perfect equality and 100 per cent maximal inequality.

Poverty gap is the mean shortfall from the poverty line (counting the non-poor as having zero shortfall), expressed as a percentage of the poverty line. This measure reflects the depth of poverty as well as its incidence.

include liberalization, macroeconomic stabilization, restructuring and privatization, and legal and institutional reforms (International Monetary Fund 2000). As these economies develop, they are increasingly integrated into global trade and their roles evolve accordingly. This has brought along opportunities as well as challenges. There are many risks of increased trade for public health, including reduced access to medicines due to extended patent protection and restriction of national governments' abilities to regulate for public health (Labonte and Sanger 2006). On the other hand, there are opportunities including improved predictability in trading health-related goods and services, technology transfer, improved efficiency in allocating health resources, and better global coordination (Smith 2006).

The Trade-Related Intellectual Property Rights (TRIPS) Agreements, despite some flexibility, demand that World Trade Organization members protect intellectual property including medicines (Avafia and Narasimhan 2006). This can effectively restrict a country's ability to manufacture or import generic drugs (UNDP and UNAIDS 2012). Although the proponents of TRIPS argue that this would encourage innovation in healthcare, there are concerns over price escalation and affordability (Bettcher et al. 2000). For example, a study in Argentina estimated that the introduction of product patents would result in price increases of about 270 per cent, a reduction in consumption of medicines by 45.5 per cent, and an increased annual expenditure of US \$194 million (Challu 1991). According to another analysis of the situation in Argentina, Brazil, Taiwan, India, Mexico, and South Korea, product patents would result in a minimum welfare loss of US \$3500 million to US \$10,800 million (Nogues 1993). One example is the effect of TRIPS on access to antiretroviral drugs (ARVs) in the fight against the AIDS pandemic in many emerging economies (Reich and Bery 2005; World Health Organization 2006).

TRIPS poses greater challenges to middle-income countries than to low-income ones. Least developed countries (LDCs) enjoy a general exemption from the TRIPS Agreement, but with a high proportion of the population still below the poverty line, middle-income countries bear the brunt of restrictions by such intellectual property enforcement. Another example is the General Agreement on Trade in Services (GATS) which can bring along opportunities, but also the risks of draining the public health workforce and misallocation of health resources (Drager and Fidler 2004).

Trade liberalization, particularly through the Uruguay Round of trade negotiation (Chaloupka and Corbett 1998), has also facilitated the penetration of tobacco industries into emerging markets. The expansion into transitional economies is a significant contributor to the increased risks of tobacco use and related diseases. As a response to declining sales in industrialized countries, major tobacco companies have targeted growing markets in Latin America in the 1960s and the newly industrialized economies of Asia (Taiwan, South Korea, and Thailand) in the 1980s (Connolly 1992).

Demography in middle-income economies

Population sizes in this group of countries vary widely. Four of the five most populous countries in the world—China, India, Indonesia, and Brazil (ranked 1st, 2nd, 4th, and 5th respectively)—that together account for nearly 3 billion persons of the world's 7 billion population in 2010, fall among this group. Two other countries, Russia and Mexico (ranked 9th and 11th respectively), together, make up in excess of another quarter billion. Countries with smaller populations account for another

164 million people, ranging from Jordan which has only six million persons to Thailand with 69 million persons.

The countries also vary in their stages of demographic development. For the majority, the transition from high to low death rate has already taken place such that in 2010, their crude death rates (CDRs) are below 10 per thousand population. Among these, Jordan has the lowest CDR (4.0 per thousand), followed by Malaysia and Mexico (4.7), Tunisia (5.6), Brazil (6.4), Indonesia (7.0), China (7.1), Thailand (7.4), and India (8.0). As the CDR is influenced by differences in population age structure, a comparison of life expectancy at birth in these countries is more reflective of their mortality transition. In 2010, the life expectancy for these countries ranged from 69 years for Indonesia to 77 years for Mexico.

South Africa and Russia are clearly outliers in this group, with crude death rates of 14.9 and 14.2 per thousand in 2010. Mortality levels in Russia have risen since the early 1990s following cataclysmic economic and political changes (Notzon et al. 1998; Men et al. 2003; Popov 2009). Life expectancy has declined as stress-related risk behaviour such as alcoholism rose and there was also an increase in violent deaths (suicides, homicides, unintentional alcohol poisoning, and traffic accidents). In the case of South Africa, there has been an increase in infectious and parasitic diseases related to AIDS. Life expectancy at birth in Russia is currently about the level in the 1960s, at nearly 69 years, after having risen to nearly 70 in the 1980s. South Africa's current life expectancy at birth, at 52 years, is well below the 61 years attained in the early 1990s.

Unlike the transition in the death rate, the transition from high to low birth rates has been less uniform, often lagging well behind the former. Thus while Jordan has the lowest CDR, its crude birth rate (CBR) is the highest, at 25 births per thousand population. With its rate of natural increase (RNI) of 21 per thousand, it is the most rapidly growing, and also the youngest, population among the group, with nearly 40 per cent aged below 15 years. Though further along in their transitions, Malaysia (CBR 20.3) and Mexico (CBR 19.5) also rank among the more rapidly growing, and youthful, countries among the group, due to lags in their fertility transition even as their death rates are among the lowest (CDRs of 4.7), bettered only by Jordan. At the other end of the spectrum, China, Thailand, and Russia are furthest along in their fertility transition, with CBRs of about 12 per thousand. Russia was the first to begin its fertility transition among this group of countries, although the transitions in China and Thailand were more rapid. All three countries are currently in the stage where they are reaping the demographic dividend, with more than 70 per cent of their populations in the working ages, 15–64 years. However, they are also furthest along in terms of the proportions of their population that are aged 65 years and older. China's and Thailand's fertility transitions appear to have been achieved at earlier stages of their demographic developments than Mexico and Tunisia: life expectancy at birth for China and Thailand, at 73 and 74 years respectively, are lower than Mexico's 77 and Tunisia's 75 years (with CBRs at 19.5 and 17.7 respectively). Russia appears to be in the post-transition stage only because of its anomalous mortality conditions.

Population density and urban agglomeration

While China is the most populous country in the world and among this group of countries, India is the most densely populated. With a population density of more than 400 persons per

square kilometre, it is well ahead of the next band of countries comprising China, Thailand, and Indonesia (in rank order), with about half the density of India. The remaining countries form another band, led by Malaysia and rounded out by Russia.

Perhaps more important for its health and infrastructural implications than absolute density is the speed and level of urbanization. While cities and urban agglomerations perform useful economic functions in concentrating wealth and talent in a particular location:

megacities are foci for risks because their unprecedented size magnifies the risks associated with any urban centre: natural disasters; infrastructure failures; pollution; poverty; shortages of food, water or fuel; crime and corruption; or social tensions. The human and economic loss potentials are much higher: not only are more people directly at risk but the repercussions of such an event will be felt by many, physically remote actors and systems, due to the interconnectedness of the megacity. (International Risk Governance Council 2010, p. 2)

Infectious diseases, non-communicable diseases (NCDs), and injuries resulting from accidents, violence, and crime are all potential health risks stemming from overcrowding, substandard housing, inadequate sanitation and waste disposal, and traffic congestion (WHO and UN-Habitat 2010).

In 2010, the level of urbanization was highest in Brazil and Jordan, with more than 80 per cent of their population living in urban areas (Fig. 1.4.1). Only Thailand and India have fewer than half of their population in urban areas, with China and Indonesia being the latest to achieve this milestone. In Thailand and India, only about one-third live in urban areas.

Concentration in agglomerations of more than 1 million persons is more likely to be found in the Latin American countries, Brazil and Mexico. While the Asian countries are generally concentrated at the lower levels along the scale of urban agglomeration (i.e. smaller proportions of their population live in cities of more than 1 million), there has been a sharp increase in China over the 1990–2010 period. Notably, there are currently more megacities in China and India than elsewhere.

Challenges and opportunities

The diverse demographic landscape among the emerging economies poses different health challenges and opportunities (see Tables 1.4.4 and 1.4.5). Rapid population growth and extremely young populations in countries that are still in the early stage of demographic transition (in Jordan, for example) present a different set of public health needs than those close to the final stages of the transition with slower growing, older populations. Rapid population growth, particularly if also highly concentrated in urban areas, is even more challenging as shown by megacities. However, there are also opportunities for those that are reaping the demographic dividend, where high fertility regimes have been followed by sharp fertility decline (as in the case of Brazil). Savings derived from having to provide for a less rapidly growing population may be better invested in higher quality of healthcare and other social infrastructure that could in turn lead to higher productivity and economic growth in a virtuous circle.

Rapid urbanization and internal migration also present critical health challenges in emerging economies. Between 1995 and 2005, the urban population of developing countries grew by an average of 1.2 million people per week (Population Division 2007). The

Fig. 1.4.1 Per cent urban population.

number of megacities has grown from two in 1950 to 20 in 2005 (Population Division 2005). In 2011, 23 urban agglomerations qualified as megacities because they had at least 10 million inhabitants (Population Division 2011). By 2025 there will be 37 megacities globally, with about 13.6 per cent of the urban population of the world living in them, up from 9.9 per cent today (Population Division 2011). Thus the public health implications of this trend will be highly significant (International Risk Governance Council 2010).

Urban health is influenced by major factors such as standards of urban governance, population characteristics, natural and built environment, social and economic environment, food security and quality, services and health emergency management (WHO and UN-HABITAT 2010). WHO, through the Commission on Social Determinants of Health (2008), has urged policymakers to place health equity at the heart of urban governance and planning, as

‘cities can also concentrate threats to health’ (WHO 2010a). WHO highlighted urban health issues including substandard housing and crowded living conditions, problems with food and water safety, inadequate sanitation and solid waste disposal services, air pollution, and congested traffic (WHO and UN-HABITAT 2010). It was also stressed that chronic diseases and mental problems resulting from unhealthy lifestyles such as unhealthy diets, sedentary behaviours, smoking, alcohol, and other substance abuse are increasingly concentrated in the urban poor (Chan 2010). Public health risks and hazards can be concentrated in urban areas, as poverty has become heavily concentrated in cities (UN-HABITAT 2010). To summarize, cities face a triple threat: infectious diseases, NCDs, and injuries resulting from accidents, violence, and crime. These public health risks are aggravated in rapid, unplanned urbanization and with growing poverty in the urban slums of many middle-income countries. An estimated 828 million people,

Table 1.4.5 Urban population statistics in middle-income countries

Country	Population in largest city (million)	Urban population growth (annual %)	Urban population (% of total)	Megacities (2011)
Brazil	20.3	1.41	86.5	2
China	16.6	2.54	44.9	4

one-third of the world's urban population, live in slum conditions, of which the vast majority of slums—more than 90 per cent—are located in the fastest growing cities of developing countries (Population Division 2007). It is of public health concern that slum dwellers experience different forms of deprivation (material, physical, social, and political) and poor access to health and other services (WHO and UN-HABITAT 2010).

The Millennium Development Goal (MDG) 7 includes a target of improving the lives of at least 100 million slum dwellers by 2020. This target has already been achieved earlier than expected and the proportion living in slums has apparently declined. According to UN-HABITAT, China and India had lifted at least 125 million people out of slum conditions between 2000 and 2010. They are the most successful countries in improving the lives of slum dwellers. Indonesia and Tunisia have also succeeded in lifting a large proportion of the population out of slum conditions (UN-HABITAT 2010). However, the absolute number of slum dwellers has risen since rapid urbanization continues to outpace slum improvements, and therefore, new and more realistic national and local targets might be required (United Nations 2011).

In addition to urbanization, internal migration is another public health challenge facing transitional countries. Some studies have pointed out inequality as a major factor driving both permanent and circular internal migration in Asian countries (Overseas Development Institute 2006). The report also highlights circular migration resulting from a lack of security in the country of destination which prevents people from settling down (Overseas Development Institute 2006). It also stressed the two-way relationship between migration and inequality, both within the poorer sending areas and between poor and rich regions (Overseas Development Institute 2006).

Recent studies on migration and health have pointed out the lack of policy coherence in addressing migration-related health issues. They revealed that most policies are narrowly focused although health intervention opportunities exist at each phase of the migratory process, including pre-departure, travel, destination, interception (temporary detention, interim residence by

immigration control), and return (Zimmerman et al. 2011). Poor people continue to migrate despite restrictive policies, as in the case of China. Although these migrations can lead to higher productivity, higher income, and economic growth, migrants are usually excluded socially, economically, and politically. Their access to health, education, housing, sanitation, protection from exploitation, child care, and schooling are limited. Migrant children, adolescent girls, and women are particularly vulnerable to exploitation and infectious diseases (Overseas Development Institute 2006).

The International Organization for Migration has detailed many challenges, including health-related issues such as poor health status, environmental health and sanitation, lack of access to health services, and vulnerability to infectious diseases including HIV/AIDS, facing internal and cross-border migrants (International Organization for Migration 2008). All of these factors can have negative impacts, either direct or indirect, on migrants' health and their access to health services.

Health indicators in middle-income countries

From a cursory overview of health indicators in middle-income countries, there are discernible comparisons. Life expectancy at birth is generally between the 60s to 70s age range, except for South Africa which is in the low 50s and also has a very high maternal mortality ratio averaging 300. Similarly, countries including India and Indonesia with high maternal mortality also have high rates of infant, neonatal, and under-5 mortality. Conversely, countries with lower maternal mortality generally have lower child mortality and adolescent fertility rates (see Table 1.4.6).

Communicable diseases in middle-income countries

While it is true that, on the whole, the proportion of deaths from communicable disease in middle-income countries is decreasing

Table 1.4.6 Health indicators in middle-income countries

Country	Life expectancy at birth	Maternal mortality ratio ^b	Neonatal mortality rate ^c	Infant mortality rate ^c	Under 5 mortality rate ^c	Adolescent fertility rate ^d
Brazil	73.1	56 (36–85)	12	17.3	19.4	75.8
China	73.3	37 (23–58)	11	15.8	18.4	8.8
India	65.1	200 (140–310)	32	48.2	62.7	79.3
Indonesia	68.9	220 (130–350)	17	27.2	35.3	43.5
Jordan	73.3	63 (37–110)	13	18.4	21.7	24.8
Malaysia	74.0	29 (12–64)	3	5.4	6.3	11.6
Mexico	76.7	50 (44–56)	7	14.1	16.7	67.5
Russia	68.8	34 (26–42)	6	9.1	11.6	25.9

as mortality due to NCDs rises (Heuveline et al. 2002; Miranda et al. 2008), communicable diseases remain a major public health challenge in these countries. Understanding communicable disease trends in middle-income countries is complex, because of the wide range of per capita incomes (O'Brien 2007) and differing health development challenges. Even within a given country, the health problems faced by the poorest 20 per cent are very different than those in the wealthiest 20 per cent. Because of this, it is possible for a single middle-income country to face a *double burden of disease*, with an increasing prevalence of NCDs despite the persistence of infectious diseases. This is particularly problematic for lower middle-income countries, where limited resources may be redirected to address the relative increase in NCDs and away from communicable disease control programmes. This would be a mistake, as the successes achieved in combating some of the most prominent communicable diseases, including tuberculosis, HIV/AIDS, and malaria can be quickly reversed.

Communicable diseases in decline in middle-income countries

The 1970s were a time of optimism that control of infectious diseases globally was at last within reach (WHO 2000). High rates of immunization against a number of childhood diseases, including diphtheria, measles, and tetanus, had had a significant impact on reducing child mortality; smallpox was at last on the verge of eradication; and a cocktail of effective antituberculosis medications made elimination seem a possibility. The emergence of the novel human immunodeficiency virus (HIV) in the 1980s, however, as well as growing resistance of tuberculosis to

available medications, provided a sombre reminder that the fight was far from over. The resurgence of previously contained infectious diseases and the increase in hospital-based antibiotic resistance provided further evidence that current containment and treatment strategies might not be sufficient for long-term control. Although the groundbreaking Global Burden of Disease (GBD) study, commissioned in 1990, proclaimed that the Group I causes of death (referring to the combination of communicable disease, maternal and perinatal disease, and nutritional deficiencies) were no longer responsible for the majority of deaths in developing regions (Murray and Lopez 1996), the World Health Report of 1996 reminded the global health community that communicable disease still played a very large role in morbidity and mortality, particularly in low- and middle-income countries (WHO 1996). This tension continues today: while the 2008 revision to the GBD, published in cooperation with the World Health Organization (WHO) and World Bank, reveals that the weight of communicable diseases among the top ten causes of death is relatively less in MICs than in low-income countries (see Tables 1.4.7 and 1.4.8), the fact remains that four of the ten leading causes of death in middle-income countries are due to an infectious cause.

A closer look at the three communicable diseases that have had the most significant health impacts worldwide helps to illustrate the overall decline of communicable disease in middle-income countries over the past decade.

HIV/AIDS

Since its identification in 1984, HIV/AIDS has caused more than 25 million deaths around the world. WHO estimates that

Table 1.4.7 Top ten causes of death in low-income countries

Cause	Deaths in millions	% of deaths
Lower respiratory infections	1.05	11.3
Diarrhoeal diseases	0.76	8.2
HIV/AIDS	0.72	7.8
Ischaemic heart disease	0.57	6.1
Malaria	0.48	5.2
Stroke and other cerebrovascular disease	0.45	4.9
Tuberculosis	0.4	4.3
Prematurity or low birth weight	0.3	3.2
Birth asphyxia and birth trauma	0.27	2.9
Neonatal infections	0.24	2.6

approximately 34 million people are currently living with HIV. In low- and middle-income countries, more than 8 million people living with HIV were receiving life-saving antiretroviral therapy (ART), over half of those eligible (UNAIDS 2012a; WHO 2012a). Although still far below international goals, this has resulted in important achievements:

- ◆ A twentyfold increase in the number of people in developing countries receiving ART in less than a decade (2003–2011) (WHO 2012a).
- ◆ An overall decrease in global AIDS-related deaths from 2.3 million in 2005 to 1.7 million in 2011 (UNAIDS 2012a).
- ◆ A more than 25 per cent decline in the rate of new HIV infections between 2001 and 2009, with above-average declines in

sub-Saharan Africa and South and South East Asia (UNAIDS 2012a).

HIV/AIDS disproportionately affects sub-Saharan Africa, the home to many low- and middle-income countries. In fact, the 20 countries with the highest HIV prevalence in 2009 were all in Africa. Of these, half were middle-income countries (UNAIDS 2012b). The top three countries with the highest absolute numbers of people living with HIV/AIDS are in South Africa, Nigeria, and India (Central Intelligence Agency 2012). The good news, however, is that of the ten middle-income countries amongst the top 20 countries for HIV prevalence rates, prevalence has decreased or remained stable in all but two since 2000 (UNAIDS 2012c). Outside Africa, middle-income countries are showing improvement as well. In India, estimated HIV prevalence decreased from 0.4 to 0.3 per cent between 2000 and 2009 (National AIDS Control Organisation 2011); it remained stable in Brazil at less than 0.1 per cent; and decreased significantly in Thailand, from 1.8 to 1.3 per cent (UNAIDS 2012d). Over that same period, however, the estimated prevalence of HIV increased from approximately 0.6 to 1.0 per cent in Russia, another highly populated middle-income country (UNAIDS 2012d); a reminder that the experience of middle-income countries in responding to infectious disease remains variable and heavily dependent on existing healthcare structures and systems.

Tuberculosis

Tuberculosis accounted for 1.4 million deaths in 2011, second only to HIV/AIDS for deaths due to communicable disease globally (WHO 2013a). The massive expansion worldwide of standardized tuberculosis diagnosis and treatment programmes (including directly observed therapy, short course, commonly referred to as DOTS) has resulted in a number of concrete successes:

- ◆ Worldwide incidence was estimated to peak in 2004, and has been gradually declining since, meeting MDG 6 (Lönnroth et al. 2010).
- ◆ Globally, more than 36 million people were cured between 1995 and 2008, with an estimated 6 million deaths avoided during that time (Lönnroth et al. 2010; Lawn and Zumla 2011).
- ◆ The case fatality rate during that period dropped by half, from 8 per cent to 4 per cent (Lönnroth et al. 2010).

It is important to recognize that the rapid increase in the world's population, particularly in middle-income countries such as China and India, means that the overall burden of tuberculosis in terms of incident cases and absolute number of deaths globally continues to increase, even though global incidence and per capita death rates have declined (Lönnroth et al. 2010). Additionally, low- and middle-income countries are disproportionately affected, accounting for 95 per cent of tuberculosis deaths. Of the 22 countries considered to have a high burden of tuberculosis, together claiming more than 80 per cent of cases worldwide, half are middle-income countries (Lönnroth et al. 2010).

The good news is that yearly incidence and estimated prevalence is stable or decreasing in nearly all of these 11 high-burden middle-income countries, with the notable exceptions of South African and Nigeria (Lönnroth et al. 2010), where tuberculosis control is complicated by very high prevalence of HIV/AIDS. The estimated death rate due to tuberculosis is generally decreasing, with significant declines noted in death rate between

1990 and 2008 in the following countries: Brazil, China, India, Indonesia, Pakistan, Russia, and Vietnam (Lönnroth et al. 2010). Similarly, the treatment success rate for new sputum-smear positive cases has met the MDG target of 85 per cent in most of these same countries, with the exception of Russia and Vietnam (Lönnroth et al. 2010). Russia's difficulty meeting the MDG target for treatment is due in large part to the very high rate of multi-drug-resistant tuberculosis (MDR-TB) there, the highest in the world at 13 per cent (Lönnroth et al. 2010). Of the 11 heavily burdened MICs, five suffer from MDR-TB rates greater than 2 per cent, with Russia, China, and India most heavily affected (Lönnroth et al. 2010).

Malaria

Malaria is the world's most deadly vector-borne disease and remains *endemic* in 106 countries as of 2010, of which 61 are middle-income countries (Roll Back Malaria 2010; WHO 2011a). Nearly half the world's population (approximately 3.3 billion) was estimated to be at risk for malaria in 2010, with an incidence rate of 219 million (WHO 2013b). Heavy investment of global development aid in highly cost-effective malaria interventions, including rapid diagnostic testing, insecticide treated nets (ITNs) and artemisinin-based combination therapies (ACTs), has resulted in substantial public health gains (WHO 2013b). Since 2000:

- ◆ malaria mortality rates have fallen more than 25 per cent globally (WHO 2011a)
- ◆ 43 of the 99 countries with ongoing malaria transmission reported greater than 50 per cent decreases in malaria incidence; an additional eight countries reported greater than 25 per cent decreases (WHO 2011a).

Where do the middle-income countries stand? On one end of the spectrum, the group of countries most heavily burdened by malaria and accounting for over 60 per cent of malaria deaths—Burkina Faso, Côte d'Ivoire, the Democratic Republic of Congo, Mali, Mozambique, and Nigeria—includes two middle-income countries (Nigeria and Côte d'Ivoire). At the other end, three of the four countries to become certified by WHO as free of malaria in the past 5 years were middle-income countries (Armenia, Morocco, and Turkmenistan) (WHO 2011a). As a group, the middle-income countries are showing significant progress in decreasing malaria incidence. While the majority of these countries remain in the control phase, one (Iraq) is in the prevention of re-introduction phase, four are in the elimination phase, and another nine are in the pre-elimination phase (WHO 2012b). Unsurprisingly, the countries in the elimination and pre-elimination phases have shown the most drastic reductions in malaria incidence since 2000; with the addition of successes in a number of countries still in the control phase, well over half the malaria-endemic middle-income countries reported decreases in malaria cases during that period. Indeed, even some middle-income countries in the control phase, such as Namibia and Nicaragua, reported decreases greater than 50 per cent (WHO 2012b).

As with tuberculosis, rising rates of drug resistance prove a significant challenge for global malaria control, including in middle-income countries. In fact, the origin of artemisinin-resistant *Plasmodium falciparum* malaria was on the border between Thailand, an upper-middle-income country, and Cambodia; this resistant form is now also suspected in Vietnam (another middle-income country) and Myanmar (WHO 2012c).

Emerging and re-emerging infectious diseases

An *emerging infectious disease* is a *pathogen* that is newly recognized as causing disease in humans. The term *re-emerging infectious disease* refers to an infectious disease already known to affect humans but which has expanded its potential range, whether by significantly increasing in incidence, re-entering a human population where it had previously been eliminated, infecting a geographic area not previously affected, or acquiring antimicrobial resistance (WHO n.d.). While any type of pathogen may infect humans, viruses are most likely to emerge as novel infectious diseases (Taylor et al. 2001; Woolhouse and Gowtage-Sequeria 2005) (see Chapter 8.17).

Factors leading to the emergence and re-emergence of infectious diseases

Several factors favour the development of emerging or re-emerging infectious diseases, of which human population growth and increasing density are two of the most important. Urbanization, characterized by large numbers of people living in close proximity and highly mobile populations, similarly poses risks for the emergence of new disease. Three-quarters of all emerging and re-emerging infectious diseases are thought to be *zoonotic* (Taylor et al. 2001), hence agriculture, animal husbandry and other food production, human encroachment on wild animal territories, deforestation, and water and sanitation all play a role in the potential for new zoonotic infections. Finally, healthcare practices at all levels, including global and national healthcare systems, pharmaceutical production, diagnosis, treatment, and patient behaviour, are important factors in the development of drug resistance.

Emerging and re-emerging infections in middle-income countries: the case of South East Asia

South East Asia, a geographic region made up of 11 countries, is a particular hotspot for emerging infectious diseases, as it acts as a melting pot for all of the factors that drive emergence. It is also the home of seven MICs: Indonesia, Philippines, Timor-Leste, Vietnam, Malaysia, Lao PDR, and Thailand. South East Asia as a whole, and Thailand and Indonesia (of the middle-income countries) in particular, were heavily impacted by the SARS (severe acute respiratory syndrome) epidemic in 2003 (Coker et al. 2011). When the *avian influenza A H5N1*, initially passed from birds to humans, broke out shortly after, there were concerns that it would similarly cause a pandemic; however, human-to-human transmission proved minimal so far. Although less publicized, the emergence of *Nipah virus* in Malaysia and Singapore in 1998 proved to be more deadly than SARS. The virus, which originated in pigs and causes severe febrile encephalitis with a case fatality rate of around 40 per cent, resulted in more than 100 deaths in these two countries (Lo and Rota 2008).

Middle-income countries in South East Asia are particularly vulnerable to the development of re-emerging infectious diseases, as well; indeed, South East Asia has been called the epicentre of antimalarial resistance. Artemisinin-resistant malaria emerged recently on the Thailand–Cambodia border, which was also the site of the emergence of chloroquine and sulphadoxine-pyrimethamine resistance in *P. falciparum* in the 1950s and 1960s (Coker et al. 2011).

All these underscore the need for stronger *surveillance systems*. These may take a variety of forms, including syndromic surveillance to identify both known and potentially novel infections;

surveillance for drug-resistance in known pathogens; and animal health surveillance. Since the emergence of SARS and H5N1, great attention has been paid toward strengthening communicable disease control in South East Asia. In Laos, for example, the government established multiple national institutions to strengthen infectious disease control, including a Centre for Laboratory and Epidemiology and a National Emerging Infectious Disease Control Office (Phommasack et al. 2012). Similarly, all the middle-income countries in South East Asia aside from Timor-Leste, are making concrete investments in strengthening their healthcare systems to more rapidly identify, contain, and control communicable diseases (Coker et al. 2011).

Challenges and possibilities for surveillance in middle-income countries

The surveillance strategies employed by middle-income countries are as varied as the group itself. Broadly, in the poorer middle-income countries, surveillance often comes behind more pressing health needs. The continuity required for a successful surveillance programme can be difficult to achieve in settings where resources are scarce and/or unpredictable. Inadequate or unevenly distributed laboratory services hinder active surveillance in some middle-income countries. Documentation of illness also varies greatly across and between countries, complicating attempts at passive surveillance.

Despite the concerns of its critics, syndromic surveillance holds potential for useful application in middle-income countries. The use of syndromic surveillance to strengthen existing measures globally was endorsed in the most recent revision of the *International Health Regulations* (IHR), internationally ratified guidelines for infectious disease notification. Specifically, the revised IHR recommend surveillance for acute respiratory syndrome, acute gastrointestinal syndrome, neurological syndrome, haemorrhagic fever, and novel severe infectious illness (World Health Assembly 2005). A number of middle-income countries have already successfully employed syndromic surveillance systems.

Non-communicable diseases in middle-income countries

With the exception of African region, the number of deaths from NCDs exceeds that from infectious diseases, maternal, perinatal conditions, and nutritional deficiencies combined. Of the estimated 57 million global deaths in 2008, 36 million (63 per cent) were due to NCDs. In 2008, around 80 per cent of all NCD deaths (29 million) occurred in low- and middle-income countries. In addition, a higher proportion (48 per cent) of all NCD deaths in low- and middle-income countries is estimated to occur in people under the age of 70 years—compared with an estimated 26 per cent in high-income countries and a global average of 44 per cent (WHO 2012d).

Top non-communicable diseases and risk factors

The leading causes of NCD deaths are cardiovascular disease, cancers, and chronic respiratory diseases. Over 80 per cent of cardiovascular and diabetes deaths, about 90 per cent of deaths from chronic obstructive pulmonary disease, and over two-thirds

of all cancer deaths occur in low- and middle-income countries (WHO 2010b). In low- and middle-income countries, 29 per cent of NCD deaths occur among people under the age of 60, compared to 13 per cent in high-income countries. The estimated percentage increase in cancer incidence by 2030, compared with 2008, will be greater in low- (82 per cent) and lower-middle-income countries (70 per cent) compared with the upper-middle- (58 per cent) and high-income countries (40 per cent) (WHO 2010b). Inadequate political commitment, insufficient engagement of non-health sectors, lack of resources, vested interests of critical constituencies, and limited engagement of key stakeholders have resulted in poor NCD prevention (WHO 2010b). WHO also pointed out that appropriate care for people with NCDs is lacking in low- and middle-income countries and populations (WHO 2010b).

Behavioural risk factors, including tobacco use, physical inactivity, unhealthy diet, and the harmful use of alcohol, are indicated to be responsible for about 80 per cent of coronary heart disease and cerebrovascular disease. Behavioural risk factors are associated with four key metabolic and/or physiological changes—raised blood pressure, increased weight leading to obesity, hyperglycaemia, and hyperlipidaemia. Every year, nearly 6 million people die from direct tobacco use and second-hand smoke. For the total population, smoking prevalence is highest among upper-middle-income countries (WHO 2010b). Tobacco use has declined in developed countries while it is rising rapidly in most developing countries, including middle-income countries. Studies from Brazil, China, India, South Africa, Vietnam, and Central America now show an inverse relationship: the prevalence of smoking is higher in low than high socioeconomic groups (WHO 2010c). Smoking rates are also rising rapidly among women, especially affluent urban young women in China, India, and Singapore (WHO 2010c). Approximately 2.3 million die each year from the harmful use of alcohol. While adult per capita consumption is highest in high-income countries, it is nearly as high in the populous upper-middle-income countries (WHO 2010b).

At least 2.8 million people die each year as a result of being overweight or obese which increase risks of heart disease, certain cancers, strokes, and diabetes (WHO 2010b). The prevalence of overweight is highest in upper-middle-income countries (WHO 2010b). Globalization and rapid urbanization have resulted in shifts towards diets high in sugar, fats, salt, and highly refined food. A recent review based on 14 surveys conducted between 1982 and 2003 in lower- to middle-income countries (Brazil, Chile, China, Cuba, India, Lithuania, Peru, Russian Federation, Samoa, and South Africa) showed the burden of obesity shifting towards individuals of lower socioeconomic status as a country's gross national product increased (Monteiro et al. 2004). This pattern is found at both individual and community level (WHO 2010c). Recent studies in Sri Lanka and India confirmed positive association, in both genders, between urbanicity and common modifiable risk factors for chronic diseases including smoking, low physical activity, low fruit and vegetable consumption, high body mass index, and high blood pressure (Allender et al. 2010, 2011).

Marketing activities for tobacco, alcohol, and junk food increasingly target people in developing countries and emerging economies (WHO 2010b). Many governments are not coping with this through policies, legislation, services, and infrastructure that could help protect their citizens from NCDs (WHO 2010b). One report estimated that losses in national income from heart

disease, stroke, and diabetes in 2005 were US \$18 billion in China, US \$11 billion in the Russian Federation, US \$9 billion in India, and US \$3 billion in Brazil (WHO 2005). A macroeconomic analysis demonstrated that each 10 per cent rise in NCDs is associated with 0.5 per cent lower rate of annual economic growth (Stuckler 2008). From 2005–2015, China and India are projected to lose International \$ (I\$) 558 billion (0.93 per cent of the GDP) and I\$ 237 billion (1.5 per cent of the GDP) respectively as a result of heart disease, strokes, and diabetes (WHO 2010b). Significant losses are also estimated for other countries. By 2025, the total direct and indirect costs from overweight and obesity alone among Chinese adults are projected to exceed 9 per cent of China's gross national product (Popkin et al. 2006). Infants and young children are getting more overweight in upper- and lower-middle-income countries than those in upper-income countries.

Selected country case: Thailand

In Thailand, according to a study by the Thai Ministry of Public Health comparing disease burden between 1999 and 2004, there was an increase in disability-adjusted life years (DALYs) due to NCDs (stroke, cancers, cardiovascular disease, chronic obstructive pulmonary disease, diabetes, cirrhosis) and mental health problems (alcohol dependence, depression) (Bundhamcharoen 2011). The study also reported a decrease in DALYs due to infectious diseases and maternal and nutritional deficiencies. Fig. 1.4.2 shows the dramatic increase in hospitalization for diabetes and heart diseases in Thailand over the last two decades (WHO 2011b).

Health systems development in middle-income countries

The pressures placed on national healthcare systems in many middle-income countries by recent demographic and epidemiological transitions are amplified by the growing demands of a more educated and affluent population for high-quality healthcare and the latest medical technologies. The demand from the expanding middle class in many higher-middle-income countries has fuelled a booming private healthcare sector. Rapid economic development is also requiring tremendous social, behavioural, and policy adjustments, and certain demographic, epidemiological,

and socioeconomic shifts are particularly accelerated for many middle-income countries. The delivery, financing, and regulatory functions of the public health system must adapt accordingly to such rapid societal changes. The need to restructure healthcare systems becomes even more critical for balancing such new demand and supply pressures (Phua and Chew 2002).

Most middle-income countries have built up capacity for basic health service delivery, according to the World Bank. They are now focusing more on the issues of universal health coverage, financial protection, and health system efficiency which face technical, institutional, and political challenges (Kremer and Besra 2002). They also face similar pressures of rising costs caused by demographic, epidemiological, and technological change; large out-of-pocket payments; inequitable and ineffective health financing systems; and inefficiencies in the healthcare system. The World Bank pointed out the need for improving equity and efficiency in tax-raising, resource mobilization, and risk pooling mechanisms to achieve universal coverage in middle-income countries. There are concerns over low-risk pooling and fragmentation which affects healthcare purchasing efficiency and equity. Fragmentation of health systems also hampers consistent policy focus and efficiency on both risk pooling and purchasing grounds. Improved pooling of out-of-pocket payments can provide middle-income countries with opportunities to mobilize substantial private resources in expanding in the risk pool. Health expenditure per capita has steadily increased in most of the middle-income countries (see Table 1.4.9).

The proportion of health expenditure by out-of-pocket payments (or direct payments) has declined in a few upper-middle-income countries, but such modes of payment still constitute a substantial proportion of health expenditure in middle-income countries. Direct payments can discourage early healthcare seeking, as many people who do seek treatment and have to pay for it at the point of delivery suffer severe financial difficulties as a consequence. The reduction in the incidence of financial hardship associated with direct payments is a key indicator of progress towards universal coverage (United Nations 2002; WHO 2002).

Examples of health system reforms in middle-income countries are discussed in World Bank publications (Gottret and Schieber 2006) and the World Health Report (WHO 2010d). Some success

stories include those of Thailand, Brazil, Tunisia, Mexico, and Columbia (WHO 2002). China has embarked on ambitious plans to provide 'safe, effective, convenient and affordable health services' to all urban and rural residents by 2020. This is part of the reforms to address the high proportion of direct payments caused by earlier market-based approaches (WHO 2002). A series of reforms has included the New Cooperative Medical Schemes, initiated in 2003 to meet the needs of rural populations, and the Urban Residents Basic Medical Insurance scheme, piloted in 79 cities in 2007 (WHO 2002). While low-income countries are still struggling to raise sufficient resources to fund essential healthcare, countries in the middle-income group are focusing on a somewhat different set of priorities. With the ability to deliver basic health services, most middle-income countries are increasingly turning their attention to the issues of universal health coverage, financial protection, and health system efficiency. These objectives require an overhaul of the current financing structures—a prospect that raises technical, institutional, and political challenges (Peabody et al. 1999).

Conclusion: investing in cost-effective public health in middle-income countries

The economies of middle-income countries face significant health challenges in the decades ahead. While communicable diseases, including HIV/AIDS, remain a serious problem, the central health issue is that all countries face a rapid rise in chronic diseases such as cancer, diabetes, and cardiovascular diseases. The rise in chronic diseases will cause suffering and premature loss of life; they are also costly to diagnose and treat, and will impose new pressures

on health budgets. The combination of increasing chronic disease and rapid population changes creates an unprecedented challenge for many middle-income economies. An essential element in the response to this challenge to growth and financial sustainability will need to be substantial but well-planned investments in health systems, perhaps of a scale not previously contemplated (WHO 2005).

In some middle-income countries, inequality in access to health services has been exacerbated by the high reliance on private resources for health financing. This heavy reliance on meeting health costs from private incomes is common to many middle-income countries (e.g. China, Indonesia, Vietnam, and the Philippines, where less than 30 per cent of health costs are met by the public sector). It contrasts sharply with the situation in developed countries and is the most notable difference in funding structure between the two groups of economies. A recent major review of studies investigating the performance of private and public sector delivery in low- and middle-income countries suggested that providers in the private sector more frequently violated medical standards of practice and had poorer patient outcomes, but had greater reported timeliness and hospitality to patients. Reported efficiency tended to be lower in the private than in the public sector, resulting in part from perverse incentives for unnecessary testing and treatment, whereas public sector services experienced more limited availability of equipment, medications, and trained healthcare workers. Competition for funding appeared between the two sectors, such that public funds and personnel were redirected to private sector development, followed by reductions in public sector service budgets and staff. The conclusions of the review do not support the claim that the private

sector is more efficient, accountable, or medically effective than the public sector, but the public sector appears to frequently lack timeliness and hospitality towards patients (Basu et al. 2012).

Role of prevention, early detection, and early intervention

Given the human, economic, and financial costs of chronic diseases, there is a strong case for increased investment in prevention and early detection and intervention: preventive programmes, including lifestyle changes and health promotion based on known risk factors (such as smoking, alcohol use, obesity, and raised blood lipid levels) and systematic monitoring of such risk factors; expanded vaccination programmes, with older proven vaccines or new ones for the emerging infectious diseases; and screening to identify and treat early preconditions for NCDs. Middle-income countries face the challenges of growing domestic capability to be able to benefit from economic progress and biomedical science research innovations, and to meet the challenge of chronic diseases and rapidly ageing populations.

Globalization

Kelley Lee

Introduction to globalization

'Globalization' is a term associated with complex and varied changes to our world, and the costs and benefits of these changes to individuals and populations are still being debated. There is now a substantial body of scholarship on globalization and public health which seeks to explain how transboundary flows of people, other life forms, goods and services, capital, and knowledge are influencing health determinants and outcomes (Lee 2003b; Kawachi and Wamala 2006; Labonte et al. 2012). The greater scale and geographical reach of these flows pose three core challenges for the public health community: how can the evidence base on globalization and health continue to be strengthened; what effective policy responses are needed to optimize globalization's benefits, and minimize its costs, to population health; and how can these policy options be practically and effectively implemented?

This chapter is concerned with how globalization is influencing public health. It begins by defining globalization and its distinctive forms in the contemporary world. The key drivers of globalization are described, alongside their resultant changes and health impacts. The chapter then focuses on how public health practice is changing as a result of globalization. Many of the issues raised in this chapter are addressed in more detail elsewhere in this textbook, reflecting the importance of globalization across many aspects of public health. The chapter concludes by considering global health governance to strengthen collective action across societies to protect and promote population health. While the public health community has found itself at the frontline of many of globalization's impacts, it continues to play a limited role in managing and shaping its future trajectory. At the same time, greater attention to the public health impacts of globalization through effective collective action across all societies to tackle transboundary health determinants and outcomes will, in turn, contribute to more sustainable forms of globalization.

What is globalization?

The widespread use of the term 'globalization' has been accompanied by variation in its definition. In many cases, the term 'global' is used interchangeably with 'international' (subjects that concern two or more countries). At other times, globalization is used to refer to specific phenomena such as the spread of fast-food restaurants to far-flung locales, the worldwide popularity of American films, or the ease of information access through the Internet. Alongside definitional vagueness lie marked differences in how globalization is normatively assessed. Some writers see globalization as a unifying and progressive force, bringing unprecedented

economic growth and prosperity to millions (Dollar and Kraay 2000). Others believe that globalization is a new form of colonialism which reinforces inequalities of wealth and power within and across countries (Cornea 2001). These different perspectives are reflected in the highly contested nature of policy analysis and scholarship in this field.

While it is beyond the scope of this chapter to review these debates in detail, it is an important starting point to approach the term critically. In the broadest sense, globalization has become widely understood as the closer integration or interconnectedness of human societies across geographical or political boundaries. While this has been the case for millennia, what is new in recent decades is the vast increase in the quantity and speed of transboundary flows, and their geographical reach. Held et al. (1999) write that it is this greater intensity and extensity of linkages across human societies that distinguish globalization today.

Three types of changes to social relations are occurring as a result of globalization (Lee 2003a). *Spatial change* refers to how people organize and interact across physical or territorial space. The familiar image of globalization as a 'global village' describes how social relations can increasingly happen on a worldwide scale. Long-haul flights, trade in foreign currencies, and the Internet are examples of social interaction across distant locations. This 'death of distance' has been driven largely by information and communication technologies of ever higher capacity, changing how we form and maintain social groups (Cairncross 2001). The creation of virtual communities, through social media such as Twitter, Facebook and YouTube, for example, allows individuals to communicate, and carry out social relations, irrespective of geographical location.

Temporal change concerns how we think about and experience time. The contemporary world is characterized by an acceleration of the timeframe in which many things can be, and are expected to be, done. For instance, global financial transactions such as foreign exchange, buying and selling equities (stocks and shares), and securing credit can take place in a matter of seconds. New modes of transportation have enabled larger numbers of people to travel greater distances in shorter amounts of time. Mechanization and scientific advances have sped manufacturing, agricultural, and construction processes.

Third, *cognitive change* concerns how we think about ourselves and the world around us. The dissemination and adoption of knowledge, ideas, values, and beliefs have become worldwide in scale through the global reach of the mass media (including the advertising industry), research and educational institutions, consultancy firms, religious organizations, and political parties. The ascendancy of English, as the leading language for diplomacy,

business, and science, is also a result of cognitive globalization. Some argue that this is leading to a dominant culture, largely of Western origin, threatening diversity and local cultures, languages, and belief systems (Barber 2003). Others believe it is allowing ‘niche’ communities to form or alternatively creating shared ideas and values such as human rights, gender equity, environmental and labour standards, and democracy (Gartzke and Li 2003). Overall, these three types of changes taking place as a result of globalization—spatial, temporal, and cognitive—are closely intertwined, and together are leading to a mixture of positive and negative impacts.

Another point of substantial debate surrounding globalization is an understanding of what is driving these change processes. Globalization is clearly enabled by technological advances which make flows across borders faster and cheaper, and hence much more pervasive. For example, the decline in freight cost per ton by sea and air freight has promoted the rapid growth of international trade (US Department of Transportation 2000; Teitel 2005) as well as the large-scale shift of manufacturing activities to low-cost countries. Not surprisingly, information and communication technologies have also been frequently cited as the major force behind globalization (Cairncross 2001; Hundley et al. 2003).

For some writers, however, technology is an enabler, but not the driver, of globalization. They argue that the real factors driving technological developments and their application are economic in nature. The global spread of capitalism has been spurred, on the one hand, by untold thousands of producers seeking access to cheaper inputs (i.e. raw materials, labour, research and development, transport and communications), most efficient (and greatest) economies of scale, and largest potential markets. Billions of consumers around the world, on the other hand, fuel this process by demanding the highest quality and quantity of goods and services at the lowest possible price. The economic transactions that result, what eighteenth-century economist Adam Smith called the ‘invisible hand’ of the market, are seen as the real force behind globalization (Dicken 1999; Schuh 2007).

A further perspective rejects globalization as an essentially technological or economically driven process which implies a degree of rationality and progress. Instead, current forms of globalization are seen as driven by particular ideologically based values and beliefs broadly referred to as neo-liberalism. It has been the global spread and dominance of this ideology from the 1980s, and its embedding within global institutional arrangements, that has, for instance, defined the industrial policies facilitating the development of such technologies (e.g. the promotion of an information economy through deregulation and privatization of the telecommunications sector), and their dissemination for particular purposes (e.g. deregulation of financial markets). It is argued that neo-liberalism has also defined economic policies which encourage trade liberalization, market-based competition, and foreign investment (e.g. tax incentives), while advocating a minimal role for the state at the expense of social welfare and environmental protections (Falk 1999). The global financial crisis from 2007 has led to a rethinking of neo-liberalism and calls for stronger global regulation (Brown and Sarkozy 2009).

Not surprisingly, differences in perspective about globalization’s drivers reflect varying views about whether, on balance, it is beneficial or costly to human societies. ‘Globalists’ (supporters of contemporary globalization) predict a world of closer integration,

shared identities, greater efficiency and productivity, rapid economic growth, and increased prosperity. While there may be bumps along the way, such as temporary inequalities in wealth within and across countries, it is believed that the globalization path is progressive in the longer term, bringing benefits for the greatest number of people. In sharp contrast, the opponents of contemporary globalization argue that there are fundamental flaws underpinning its logic in the form of stark imbalances in wealth and power which immutably divide the world into a few winners (those with access to technology, capital, knowledge, and gainful employment) and many losers. Although globalization may increase total wealth, critics challenge the assumption that this wealth will eventually ‘trickle down’ the global pecking order. Rather, it is argued that without strong commitment to redistributive policies, along with social and environmental protections, neo-liberal globalization will widen the gap between ‘haves’ and ‘have-nots’ (Mittelman 2002). In this sense, contemporary globalization is socially (Bacchetta and Jansen 2011) and environmentally unsustainable (Martens and Raza 2010).

From a public health perspective, there is strong evidence that globalization is leading to diverse and complex changes to health determinants, resulting in both positive and negative health outcomes for different populations. For the protection and promotion of population health, and as part of the longer-term sustainability of globalization, these changes must be actively managed to minimize the costs, and maximize the benefits, as well as ensuring that the costs and benefits to public health are equitably shared across societies. In order to develop effective responses to the public health implications raised by globalization, it is useful to consider in greater detail what changes are taking place and how they relate to public health.

Features of contemporary globalization

Globalization and the world economy

Current forms of globalization are characterized by the closer integration of systems of economic production, distribution, and consumption on a worldwide scale. While economists have varied opinions on the precise timing of these processes, most agree that the creation of the Bretton Woods Institutions—the World Bank, International Monetary Fund (IMF), and General Agreement on Tariffs and Trade (GATT)—after the Second World War laid its institutional and normative foundations. Each has played an important role in facilitating the emergence of a global economy defined by the liberalization of capital flows, and opening of national markets to trade and investment.

The first major pillar of a globalized world economy, the liberalization of capital flows, was introduced in the United States from the mid 1970s which, in turn, precipitated a complete restructuring of financial markets worldwide. Historically, banks, insurance companies, investment companies, and brokerage firms have been subject to heavy regulation. Deregulation of financial markets, such as the removal of restrictions on the types of securities that financial institutions could trade, levels of interest that could be paid on specific types of securities and bank accounts, and types of institution entitled to act as financial intermediaries, was introduced to increase competition and encourage capital flows within and across countries. Information and communication technologies enabled high-speed electronic-based transactions

which eventually linked financial markets across countries. The result has been a globally integrated financial market capable of 24-hour trading in foreign exchange, commodities, capital, and other financial assets (Valdez 2006). The world's financial assets have correspondingly boomed, from US \$136 trillion in 2005 to US \$198 trillion in 2010. By 2020, this is expected to rise to US \$371 trillion, with one-third accounted for by emerging economies (Roxburgh et al. 2011).

A second key pillar is the trade of goods and services. While trade has been the lifeblood of commerce for thousands of years, it is the global restructuring and integration of production, accompanied by the increased scale and scope of trade, which characterizes the world economy of recent decades. Historically, trade among countries has been dominated by raw materials and natural resources (e.g. oil, timber), commodities (e.g. grains, metals), or manufactured products (e.g. textiles and clothing, food products). In 1948, the GATT was established as an agreement under which signatories could negotiate reductions in tariffs on traded goods. Eight trade rounds were carried out between 1948 and 1994 by which thousands of tariff reductions were negotiated. During this period, membership grew from 23 countries in 1947 to 125 countries in 1994, thus establishing a worldwide trading system.

The growth of international trade led to renewed support for a permanent organization, resulting in the creation of the World Trade Organization (WTO) in 1995. As of 2012 there are 157 member states, with many more countries seeking accession. Moreover, the WTO's remit embraces trade in services, agriculture, intellectual property rights, government procurement, and other areas (Wilkinson 2006). The overall effect has been that world trade has grown faster than world output. In 2006, for example, world merchandise exports increased by 15 per cent to US \$11.76 trillion, and commercial services exports grew by around 11 per cent (US \$2.71 trillion), compared with global gross domestic production (GDP) growth of 3.7 per cent (WTO 2007). The global financial

crisis from 2008 has led to a significant downturn in trade volumes but the overall trend has been sharply upwards (WTO 2012).

The global restructuring of production and exchange processes has been an integral part of the boom in international trade over the past half century. In many sectors, transnational corporations (TNCs) have emerged which have relocated components of their business to different parts of the world. Thus, resource extraction may take place in one country, manufacturing in another, and research and marketing in still others (Dicken 1999). The targeted consumers have also changed, with TNCs seeking markets worldwide for global brands. According to the European Brand Institute (2012), the five most valuable global brands are Apple, Coca Cola, Microsoft, IBM, and Google.

Global economic restructuring can be observed in many sectors with direct or indirect impacts on public health. One important example is the pharmaceutical industry which is now dominated by a small number of large companies formed through mergers and acquisitions. The buying of domestic generic and manufacturing companies to access emerging markets, and the consolidation of the pharmaceutical and biotechnology industries, have been particular trends since 2008 (IMAP 2010). Table 1.5.1 describes the largest pharmaceutical companies in 2011 by revenue. In 1992, the ten largest companies accounted for one-third of world revenue (Tarabusi and Vickery 1998). By 2011, this had increased to 46 per cent. This trend towards consolidation has been driven by global competition. The cost of research and development (R&D), large-scale manufacturing, and worldwide marketing and distribution means that successful companies need to be of a certain size with considerable resources. For example, the reported cost of developing and bringing a new drug onto the market now averages US \$4 billion, taking into account total R&D spend versus the number of actual new products (Herper 2012).

The tobacco industry offers another health-related example of the global restructuring of the world economy. As smoking prevalence has declined in the 'traditional markets' of North

Table 1.5.1 World's ten largest pharmaceutical companies (2011)

Company	HQ	Revenue (millions US\$)	Growth (%)	Market share (%)
Pfizer	United States	57,747	-1	6.6
Novartis	Switzerland	47,935	10	6.0
Merck	United States	41,289	7	4.7
Sanofi Aventis	France	42,779	3	4.6
AstraZeneca	United Kingdom	32,981	3	4.3
Roche	Switzerland	34,900	6	4.0
GlaxoSmithKline	United Kingdom	35,594	1	4.0
Johnson & Johnson	United States	24,368	0	3.2
Abbott	United States	22,435	7	3.0
Teva	Israel	16,689	-2	2.8
Total				43.2

America, Europe, and Australia/New Zealand, the industry has focused on emerging markets in Asia, Middle East, Eastern Europe, Latin America, and Africa. Consequently, through mergers and acquisitions, the industry has become dominated by four transnational tobacco companies (TTCs)—Philip Morris, British American Tobacco, Japan Tobacco International, and Imperial Tobacco—controlling around 62 per cent of the world cigarette market by volume in 2008. This excludes the Chinese National Tobacco Corporation, a state monopoly, which accounts for 37 per cent of the world cigarette market, but concentrated on supplying 98 per cent of the 300 million smokers in China (WHO 2012b). Importantly, globalization has facilitated the tobacco industry's expansion into emerging markets through trade liberalization, foreign direct investment, increased economies of scale and marketing of global brands (McGrady 2012).

The public health consequences of economic globalization relate to the availability of health promoting or harming goods and services. In the pharmaceutical industry, consolidation can lead to improved efficiencies, R&D investments, distribution and safety of drug products. However, so-called 'Big Pharma' can also focus on the most profitable products and markets to recover high investment costs. The public health community has become concerned about the neglect of diseases and populations deemed to offer insufficient financial returns. For conditions where there are a relatively small number of sufferers, or the affected population is unlikely to afford cost-recovery level prices, companies may invest limited resources (Trouiller et al. 2002). For drugs reaching the market, affordability becomes a concern because patent-protected drugs are often too costly for patients in developing countries. The need to balance access to medicines with IPR protections led to the 2001 Doha Declaration on Intellectual Property Rights and Public Health, followed in 2003 by the WTO's Decision on Implementation of Paragraph 6, both intended to clarify flexibilities in the Agreement on Trade-Related Intellectual Property Rights permitting member states to take measures, such as compulsory licensing, that improves access to medicines (Kerry and Lee 2007). The formation of a WHO Commission on Intellectual Property Rights, Innovation and Public Health in 2003, investment by a few companies in 'rare disease' strategies and drug development for diseases in developing countries, and innovative financing schemes have sought to address the tension between industry interests and health equity goals.

The globalization of the food industry has raised widespread public health concerns about the rise in non-communicable diseases (NCDs) worldwide. Changing dietary patterns are one of multiple factors, notably physical inactivity, tobacco and alcohol use, and built environments, that must be better understood. The increased production and consumption of processed foods, for example, has increased salt intake and consequently hypertension among populations worldwide (Brown et al. 2009). The stark rise in adult and childhood obesity has been attributed to the availability and affordability of 'energy dense' foods (high fat and sugar) (Drewnoski 2007). Lang et al. (2006) assessed compliance by 25 of the world's largest food manufacturers and retailers to recommendations concerning ingredients, advertising, portion size, and labelling. Only a small proportion of companies are voluntarily reducing salt, sugar, and fats in their products. While the public health community has pushed for stronger regulation, governments to date have favoured industry initiatives such as

voluntary codes. The 2004 WHO Global Strategy on Diet, Physical Activity and Health was also given no regulatory 'teeth' by member states, and the political declaration of the 2011 UN High Level Meeting on Non-Communicable Disease Prevention and Control has 'failed to generate the sustained popular attention and donor resources' (Johnson 2012).

Governments worldwide have committed to stronger tobacco control given 6 million deaths annually, rising to 8 million by 2030 (WHO 2012a). Of particular concern is the expansion of TTCs into the developing world where 70 per cent of tobacco deaths will occur in future. The WHO Framework Convention on Tobacco Control (FCTC) signed in 2003 sets out minimum measures that States Parties commit to. In addition, a Protocol to Eliminate Illicit Trade in Tobacco Products, representing 20–25 per cent of total consumption, was agreed in 2012.

Cigarette smuggling is part of a range of illicit activities, facilitated by globalization, which have direct implications for public health. Illegal psychoactive drugs, with a street value of US \$322 billion in 2003, account for one in 100 adult deaths. Around 230 million people (or 5 per cent of the global population age 15–64) used illicit drugs at least once in 2010. In recent decades, the trade has become globalized in terms of producers and consumers, and the transboundary network of criminal organizations that connects them (United Nations Office on Drugs and Crime 2012). A related problem is counterfeit goods which comprise 5–7 per cent of world trade. Many counterfeits, notably medicines, food products, and cigarettes, are of dubious quality and content, and pose direct risks to public health. Counterfeit baby milk powder in rural China caused the deaths of 50 children and acute malnutrition in hundreds of others (Watts 2004). WHO estimates that counterfeit drugs account for 10 per cent of all pharmaceuticals, a figure much higher in some developing countries. For example, 80 per cent of drugs distributed by major pharmacies in Lagos, Nigeria were found to be counterfeit (WHO 2006a).

Population movements amid globalization

Globalization has been characterized by unprecedented levels of population movements in terms of frequency and distance travelled. Population movements are not new—humankind has been on the move since *Homo erectus* migrated out of Africa in about 1 million BC. What characterizes population mobility since the mid twentieth century has been its volume, geographical reach, speed, and frequency, resulting in what Castles and Miller (2009) call the 'age of migration'. International migration totals 214 million people per year (3.1 per cent of the world's population), an increase from 150 million in 2000 (UNDESA 2008). Two million people cross international borders daily, and 500 million people cross borders on commercial airlines annually. By 2012, 215 million people lived outside their country of birth, compared with 156 million in 1990 (UNCSD 2012).

The reasons why people migrate are diverse. For the relatively educated, highly skilled, and mobile, globalization offers new employment opportunities. For the poorly educated and low skilled, globalization has brought employment insecurity. In healthcare, this trend is evident in the migration of health workers. While health worker migration from poorer countries, notably sub-Saharan Africa, to the industrialized world has received much needed attention, migration patterns are complex. The decision to migrate is an individual one, based on personal circumstances

and employment prospects, but broader forces shaped by globalization, affecting work and living conditions, are also at play (Bach 2003). The *World Health Report 2006* (WHO 2006c) estimated there are 59.2 million full-time paid health workers worldwide, with an estimated shortage of 4.3 million doctors, midwives, nurses, and support workers. This shortage is most critical in 57 countries, especially sub-Saharan Africa and South East Asia. The African region, for instance, has 24 per cent of the global health burden but only 3 per cent of health workers. This ‘brain drain’ of health workers from low- to high-income countries, has gravely worsened this problem. On average one in four doctors and one in 20 nurses trained in Africa is working in OECD countries.

The unprecedented speed and scale of urbanization worldwide over the past three decades raises profound challenges for public health. Globalization has accelerated the formation of mega-cities throughout the developing world, characterized by vast inequalities in income, living standards, environmental conditions, and life chances. In the Asia and the Pacific region over the last two decades, the urban population has risen by 29 per cent, and growing at 2 per cent per annum, reached 43 per cent in 2010. Africa is the least urbanized region but has the highest urban population growth in the world, at an average annual rate of 3.5 per cent (2005–2010). Latin America, in contrast, is the most urbanized at 80 per cent, a proportion predicted to rise to 90 per cent by 2050 (UN HABITAT 2012). In many countries, governments are struggling to provide appropriate infrastructure such as housing, water and sanitation, healthcare, transportation, security, and education that underpin health and well-being (Moore et al. 2003).

The implications of globalization for core public health functions

Public health is concerned with improving the health of whole populations within and across countries (Walley et al. 2001, p. 19).

As part of the review and renewal of public health systems worldwide since the late twentieth century, there has been much reflection on core public health functions. The Institute of Medicine (1988), for example, initiated a debate in the United States in its report, *The Future of Public Health*, later updated amid existing challenges such as ‘obesity, toxic environments, a large uninsured population, and health disparities’, with ‘emerging threats’ caused by rapid changes to the nation’s social, cultural and global contexts, scientific and technological advances, and demographic shifts (Institute of Medicine 2002). The US Health and Human Services Public Health Service (1995) identifies ten core activities of public health such as preventing epidemic; protecting the environment, workplace, food and water; and promoting healthy behaviour. In the United Kingdom, the creation of a ‘new public health system’ in 2011 has led to reforms that delineate responsibilities between local authorities and Public Health England (UK Department of Health 2011). Similar reflection is being undertaken in a diverse range of countries including India (Planning Commission of India 2011), Brazil (Jerberg 2008), and China (2009). Fig. 1.5.1 illustrates the core functions for public health identified by the Ministry of Health for the Canadian province of British Columbia.

An important impetus for recent debate has been the need to adapt core public health functions to rapid globalization. As described earlier, spatial, temporal, and cognitive changes arising from globalization are having important impacts on population health determinants and outcomes. Globalization is not only leading to public health issues transcending national boundaries, but also to the need for collective efforts across countries to help shape more socially just and sustainable forms of globalization. Drawing on Fig. 1.5.1, the remainder of this chapter examines some of these core functions, how globalization may impact on their practice, and how the public health community might effectively respond to these impacts (Beaglehole and Bonita 2010).

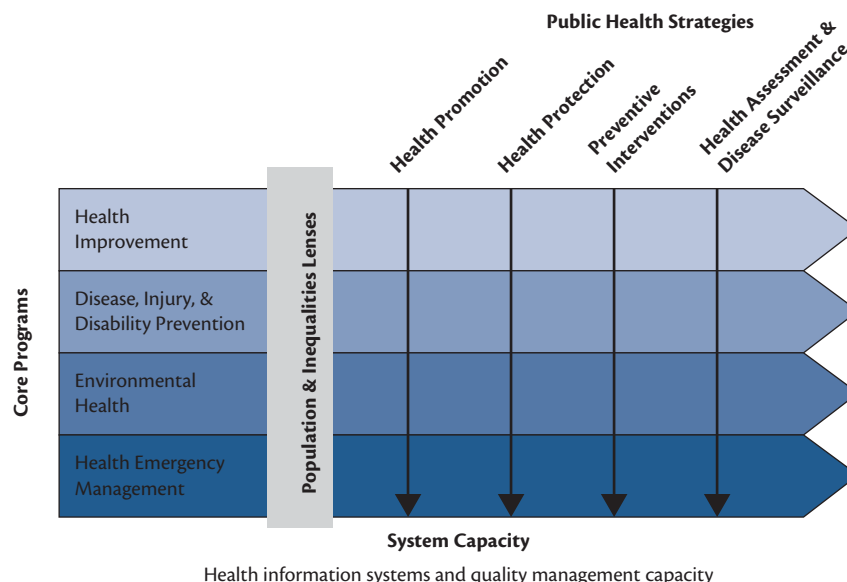

Fig. 1.5.1 Core functions framework.

Globalization and disease prevention and control

The prevention and control of disease is a core public health function. Historically, disease-causing microbes have travelled across vast distances for as long as human populations have come into contact with each other and other animal species. For example, the shift from hunting-gathering to agrarian societies and the domestication of animals, between 8000 and 3500 BC, led to the emergence and spread of new zoonotic diseases (Swabe 1999). The so-called ‘Columbian exchange’, following the arrival of Christopher Columbus in the Americas, is noted for the widespread exchange of plants, animals, foods, human populations (including slaves), and ideas that followed. Diseases, such as cholera, influenza, measles, malaria, smallpox, and tuberculosis, were also exchanged, resulting in the decimation of indigenous populations (Crosby 1972). Another notable example is the influenza pandemic of 1918–1919 which killed around 25 million people, demonstrating the capacity of infectious disease to spread worldwide amid large-scale human migration and weakened societies.

Contemporary globalization is creating new risks of disease outbreaks with a greater capacity to spread more rapidly and further afield. First, globalization may alter population size at risk of disease. Rapid urbanization, without sufficient attention to housing, clean water and sanitation, and access to healthcare, is creating large populations vulnerable to disease outbreaks. The world’s urban population will almost double from 3.3 billion in 2007 to 6.3 billion in 2050, with most of this growth in cities within the developing world as hubs for the worldwide transmission of infectious diseases (Alirol et al. 2010). In cases where global population mobility comes together with local poverty, such as the arrival of UN soldiers from Nepal in 2010 to earthquake affected Haiti, diseases such as cholera have an opportunity to spread (Doyle 2012).

Importantly, globalization can also ‘democratize’ disease risks by making larger populations vulnerable. While tuberculosis and cholera are historically associated with the poor, other diseases do not discriminate by socioeconomic class. The rapid international response to the severe acute respiratory syndrome (SARS) outbreak in 2002–2003 was due to the recognized vulnerability of all populations, rich or poor, across the world (Woollacott 2003). The spread of SARS, from China to around 25 countries within weeks, illustrated how quickly infectious diseases can spread in a globalized world. There remain concerns about avian influenza (H5N1) causing a lethal human pandemic of unprecedented speed and reach (Lee and Fidler 2007). The 2009 H1N1 influenza pandemic had a lower case fatality rate than initially feared, but illustrated how such a pandemic could spread in a globalizing world.

Second, globalization may influence the *prevalence* (number of people with a disease within a given population) and *incidence* (number of new cases of a disease in a specified period of time per total population) of certain diseases. De Vogli and Birbeck (2005) argue that vulnerability to HIV/AIDS, tuberculosis, and malaria is closely linked to poverty, gender inequality, development policy, and health sector reforms that involve user fees and reduced access to care. Dorling et al. (2006) similarly argue that ‘global inequality in wealth will have compounded the effects of AIDS on Africa’, notably caused by globalization-related policies such as structural adjustment programmes. Changing employment patterns and conditions, as a result of economic globalization, have also had epidemiological consequences. Moody (2007) describes

the globalization of the mining industry and its impact on local communities. Basu et al. (2009) observe how tuberculosis incidence among southern African miners is ten times greater than the general population, with migration to and from mines amplifying tuberculosis epidemics in the general population.

Third, globalization may increase the risks from emerging and re-emerging diseases. Environmental degradation, such as rainforest destruction and intense farming methods, can bring human and animal populations into closer contact. Sixty per cent of emerging infectious diseases that affect humans are zoonotic (originating in animals), and more than two-thirds of those originate in wildlife including HIV/AIDS, West Nile, Lyme disease, and Nipah virus. A 2012 study by the International Livestock Research Institute found that five countries—Bangladesh, China, Ethiopia, India, and Nigeria—are hotspots of poverty and zoonoses. The study also found that the northeastern United States, western Europe (especially the United Kingdom), Brazil, and parts of South East Asia may also be hotspots of ‘emerging zoonoses’—those that are newly infecting humans, are newly virulent, or have newly become drug resistant (Grace et al. 2012).

The heightening of disease risks within a globalizing world has prompted efforts to develop more effective public health responses. Alongside risks, globalization brings opportunities to improve the capacity of public health institutions to respond more effectively to infectious disease outbreaks. Foremost is the advent of new information and communication technologies which, in principle, enable faster, cheaper, and more efficient gathering and sharing of knowledge. ProMED-mail (see Box 1.5.1) and regional disease

Box 1.5.1 Programme for Monitoring Emerging Diseases (ProMED-mail)

ProMED-mail—the Program for Monitoring Emerging Diseases—is an Internet-based reporting system dedicated to rapid global dissemination of information on outbreaks of infectious diseases and acute exposures to toxins that affect human health, including those in animals and in plants grown for food or animal feed. Electronic communications enable ProMED-mail to provide up-to-date and reliable news about threats to human, animal, and food plant health around the world, 7 days a week. By providing early warning of outbreaks of emerging and re-emerging diseases, public health precautions at all levels can be taken in a timely manner to prevent epidemic transmission and to save lives.

ProMED-mail is open to all sources and free of political constraints. Sources of information include media reports, official reports, online summaries, local observers, and others. Reports are often contributed by ProMED-mail subscribers. A team of expert human, plant, and animal disease moderators screen, review, and investigate reports before posting to the network. Reports are distributed by email to direct subscribers and posted immediately on the ProMED-mail web site. ProMED-mail currently reaches over 60,000 subscribers in at least 185 countries.

Reproduced with permission from the International Society for Infectious Diseases, *About ProMED-mail*, Copyright © 2013 International Society for Infectious Diseases. All rights reserved. Available from <http://www.promedmail.org/pls/promed/f?p=2400:1950:17654933971171386906>.

surveillance networks have facilitated the collection and reporting of epidemiological data. The lessons learned from SARS led to renewed efforts to revise the International Health Regulations (IHR), which came into effect in 2007, to harness a broader range of information sources. Another change is the expansion of the scope of the IHR beyond named diseases, notably plague, yellow fever, and cholera, to the broader term 'public health emergencies of international concern'. This may include human or natural disasters. Beyond surveillance, technological advances are also permitting faster development, such as drugs, vaccines, because of the capacity for more rapid development and testing, and potential dissemination of new knowledge within the medical research community (WHO 2005).

Protecting the natural and built environmental health in a global context

The discipline of environmental health concerns 'the theory and practice of assessing, correcting, controlling, and preventing those factors in the environment that can potentially affect adversely the health of present and future generations' (Pencheon et al. 2001, pp. 206–7). Environmental threats to public health range from local, small-scale factors (e.g. household exposures) to widespread exposures affecting whole populations. Protecting against a perceived environmental health threat involves identifying the hazard, determining the relationship between the hazard and the effect (dose–response assessment), exposure assessment, and risk characterization.

The possible impacts of globalization on environmental health are wide-ranging, potentially affecting populations at the global, regional, community, occupational, and household levels. These impacts can be direct, such as through the dumping of hazardous waste across borders, relocation of risky occupations (such as ship breaking or asbestos disposal in low-income countries), damage caused by acid rain, or a nuclear accident. Economic globalization, in which companies compete on a worldwide scale to increase returns, is raising concerns that profit-maximization motives can undermine environmental health. Governments, seeking to attract foreign direct investment to fuel economic growth and generate employment, are accused of engaging in a 'race to the bottom' by offering reduced taxation rates, lower wages, or weaker environmental, health and safety protections, although much depends on the domestic context and policies of neighbouring countries (Mosley and Uno 2007). As stated by the environmental organization, the Sierra Club (1999), 'By promoting economic growth without adequate environmental safeguards, trade increases the overall scale and pace of resource consumption; promotes adoption of high-consumption, high-polluting lifestyles; and prompts countries to seek international advantage by weakening, not raising, environmental protections'.

The World Bank (2000) argues that '[e]very society has to decide for itself on the relative value it places on economic output and the environment'. Others argue, however, that there are substantial inequities in terms of who bears the environmental costs. In addition, many of the environmental impacts can affect more than one country and can even be global in scope. More commitment is thus needed to better balance the trade-offs between economic growth and environmental protection, including a fuller understanding of environmental health risks.

In managing such trade-offs, the indirect effects of globalization on environmental health must also be recognized. A change in investment or lending policy by a global financial institution, such as the IMF, can have health consequences for local communities. For example, policy conditions set by the World Bank, or requirements to repay substantial sums of foreign debt, can restrict the public expenditure of borrowing countries on environmental protection or investment in basic infrastructure, such as water and sanitation. A cholera outbreak in South Africa in 2000–2001, which led to around 120,000 cases and 265 deaths, has been blamed on the introduction of user fees following the privatization of water utilities as part of the country's structural adjustment programme. As water supplies were cut to poor people unable to pay for the new charges, many resorted to using polluted river water (Anonymous 2006). Today, more than 2.6 billion people—over 40 per cent of the world's population—do not have access to basic sanitation, and more than 1 billion people still use unsafe sources of drinking water (WHO/UNICEF 2006). Predictions of the growing scarcity of fresh water supplies globally, and the continued trend towards the privatization of water utilities with ownership dominated by large TNCs, is likely to worsen this situation.

The capacity of the public health community to correct, control, and prevent environmental health risks can be affected by globalization. For example, globalization poses additional challenges for identifying a hazard and its causal relations. The tasks associated with identifying a hazard must take account of factors that extend far beyond national borders, a greater range of stakeholders, and jurisdictions that lie beyond the reach of public health authorities. A good example is the increase in reported outbreaks of food-borne illnesses involving more than one country which has been linked, in part, to the globalization of the food industry (Kafarstein et al. 1997; Hall et al. 2002). Tracing the source and cause of such an outbreak can be hindered by inadequate record-keeping in some countries, lack of timely sharing of information, inconsistency in labelling, or lack of access to production facilities abroad. The work of environmental health workers can be made even more difficult by hazards arising from illicit activities such as dumping, counterfeiting, or smuggling across borders (Kimball 2006).

The undertaking of risk assessment, defined as 'the process of estimating the potential impact of a chemical, physical, microbiological, or psycho-social hazard on a specified human population or ecological system under a specific set of conditions and for a certain timeframe' (Pencheon et al. 2001, p. 208), is also made more challenging by globalization. The population of interest may be widely dispersed, because of their mobility or transience, and identifying and measuring a suspected hazard requires large-scale analysis. Weiland et al. (2004) study 650,000 subjects as part of the International Study of Asthma and Allergies in Childhood. A collaboration among 155 participating centres worldwide, it is the first study 'to take a global view [of] ... the relationship between asthma and eczema and climate' (Graham 2004).

Growing evidence suggesting that globalization is creating new environmental conditions, in which disease can emerge and spread more readily geographically and across species, has led to support for the so-called One Health approach. Ever growing human populations, reaching 7 billion in 2011 (UNFPA 2011), and the resulting environmental degradation from expanding land

use, intensified agricultural and animal husbandry methods, and closer contact between humans and both domesticated and wild animal species, are recognized as key factors increasing shared risk across the animal–human–ecosystem interfaces (Ostfeld 2009; Sherman 2010). The concept of ‘One Medicine’ was coined in 1984 by the ‘father of veterinary epidemiology’ Calvin Schwabe (1984) who in his book *Veterinary Medicine and Human Health*, argued that ‘the critical needs of man include the combating of diseases, ensuring enough food, adequate environmental quality, and a society in which humane values prevail’. Schwabe renewed the basic principle that a more holistic approach to human, animal, and environmental health was needed to better protect the health of all. Known as One Health, this approach has received growing attention over the past decade among policymakers, practitioners, and funders seeking more effective prevention, control and treatment responses in an increasingly populous and globalized world.

Harnessing new global information and communication technologies for public health

A key defining feature of contemporary globalization has been the spread of information and communication technologies (ICTs) worldwide, transforming almost every aspect of human life. Beginning with the advent of the personal computer in the 1980s, ever increasing processing speeds and storage capacity has led to the creation of new devices offering a wide range of mass applications at cheaper prices. Economic globalization has been enabled by the application of global networks of high-capacity computer systems which enable 24-hour financial systems and trading at an unprecedented scale and speed. Population mobility has been facilitated by online travel booking and the use of mobile technologies. How we work, shop, entertain and educate ourselves, and even form our individual and social identities, are all changing as a result of ICTs.

The global reach and application of ICTs are having profound impacts on health determinants and outcomes. The delivery of healthcare in many countries is being transformed by ICTs including research, diagnostics, patient care, planning and management, informatics, and health promotion. Often known as eHealth (or electronic health), technological change has been spurred by the increased complexity of health systems, need to manage ever larger and more complex datasets, rising cost of healthcare, need to provide longitudinal and comprehensive health records for individual patients, and increased mobility and/or geographically dispersal of many patient populations and healthcare providers. ICTs have been identified as particularly effective, for example, at reaching more individuals with effective health-related advice and information at a very low cost (Strecher 2007).

The use of mobile and wireless technologies in health (known as mHealth), in particular, has grown rapidly with advances in technologies and applications (or ‘apps’), the declining cost of handsets and data transmission, and growth cellular network coverage. According to the International Telecommunication Union (ITU), there were over 5 billion wireless subscribers, over 70 per cent residing in low- and middle-income countries, in 2010 (ITU 2010). Commercial wireless signals cover over 85 per cent of the world’s population, extending far beyond the reach of the electrical grid (WHO 2011). The potential for mHealth in low- and middle-income countries to improve healthcare, hindered in the

past by a lack of infrastructure, is thus promising. Initiatives such as the mHealth Alliance (<http://www.mhealthalliance.org/about>) are seeking to catalyse the expanded use of such technologies in global health.

Social media, ‘interactive platforms via which individuals and communities create and share user-generated content’ (Kietzmann et al. 2011, p. 241), has also seen the blossoming of health-related applications. A systematic review of social media and public health messages finds that, as more consumers turn to the Internet for health-related information, health organizations have begun to use social media for connecting with the public (Newbold and Campos 2011). For example, health insurance companies are applying social media, health gaming apps, and other mobile apps to increase patient engagement in their own healthcare (Chilmark Research 2012). Evidence suggests considerable reach associated with social media applications, and the potential for engaging specific target audiences, although efficacy of public health messaging requires further investigation through controlled studies (Newbold and Campos 2011).

Overall, ICTs offer much promise for public health application. There has been substantial investment in such technologies by governments and the private sector, alongside promises to transform practice. However, a systematic review of eHealth technologies, and their impact on the quality and safety of healthcare delivery, found a lack of evidence about their benefits and cost-effectiveness (Black et al. 2011). Alongside their adoption by the public health community has been their use for commercial purposes to shape consumer choices and behaviour, many of which have impacts on the broad determinants of health. The online marketing and promotion of health-related goods and services has spread rapidly and, in many cases, been weakly regulated. The global reach of direct-to-consumer marketing of pharmaceuticals, authentic and counterfeit, via the Internet has been a particular source of regulatory concern. The challenge to national authorities of regulating Internet marketing and sales to ensure safety and efficacy of health-related goods arises from the transboundary nature of such transactions. How to strengthen regulatory mechanisms worldwide, notably in countries where such goods originate, has been the focus of growing policy debate (Institute of Medicine 2012). Greater scrutiny of such technologies and their uses remains much needed.

Globalization and health promotion

The rising burden from NCDs worldwide in recent decades (Beaglehole and Yach 2003; Matthews and Pramming 2003) has led to growing recognition of global approaches to health promotion (Lee 2007). NCDs are the leading causes of death and disability worldwide. Their prevalence rates are accelerating globally, in every region, and across all socioeconomic classes. Chronic diseases account for an estimated 60 per cent of all deaths worldwide (or 43 per cent of the global burden of disease), with 80 per cent occurring in low- and middle-income countries. By 2020, these figures are expected to rise to 73 per cent of all deaths and 60 per cent of the global burden of disease (Daar et al. 2007). Four chronic diseases—cardiovascular diseases (CVD), cancer, chronic obstructive pulmonary disease, and type 2 diabetes—are linked by common and preventable biological risk factors, notably high blood pressure, high blood cholesterol, and overweight, and by

related major behavioural risk factors (unhealthy diet, physical inactivity, and tobacco use). Preventing these diseases should focus on controlling key risk factors in a well-integrated manner (WHO 2009b).

Health promotion is the process of enabling people to increase control over, and to improve, their health (WHO 1986). Interventions address three areas of activity in order to prevent disease and promote the health of a community: communication, service delivery, and structural (enabling factor) components (Walley et al. 2001, p. 147). A global approach to health promotion takes into account the ways in which globalization may be influencing the broad determinants of health, and health behaviours, as well as offering opportunities for providing appropriate interventions. The adoption of the Bangkok Charter for Health Promotion in a Globalized World in 2005 was in recognition of the major challenges, actions, and commitments needed to address the determinants of health in a globalized world by reaching out to people, groups, and organizations that are critical to the achievement of health. How this might be achieved can be understood in relation to two key issues—obesity and tobacco control.

The rapid increase in overnutrition and obesity, among both adults and children, has attracted substantial public health concern in recent years. According to WHO (2012a), around 500 million people worldwide are obese (body mass index (BMI) >30), with levels rising rapidly in the twenty-first century. At least 200 million school-age children are overweight or obese, with 40–50 million classified as obese (International Association for the Study of Obesity 2010). Importantly, these upward trends are not limited to high-income countries. Changes in diet, levels of physical activity, and nutrition have led to sharp increases in obesity rates in such wide-ranging countries as India, Thailand, Brazil, and China. Drewnoski and Popkin (1997, p. 32) write:

Whereas high-fat diets and Western eating habits were once restricted to the rich industrialized nations... the nutrition transition now occurs in nations with much lower levels of gross national product (GNP) than previously.... First, fat consumption is less dependent on GNP than ever before. Second, rapid urbanization has a major influence in accelerating the nutrition transition.

Similarly, Prentice (2006, p. 93) links the trend to globalization of food production and lifestyles:

The pandemic is transmitted through the vectors of subsidized agriculture and multinational companies providing cheap, highly refined fats, oils, and carbohydrates, labour-saving mechanized devices, affordable motorized transport, and the seductions of sedentary pastimes such as television. This trend has been linked to the globalisation of sedentary lifestyles alongside changes in food production and consumption.

Many interventions to address the obesity epidemic have focused on the modification of individual behaviours, such as healthy eating initiatives and the promotion of physical activity. Global health promotion, however, would also seek to tackle the structural factors that constrain or enable lifestyle choices. This includes what and how food is produced and marketed by a globalized food industry. For example, the Institute of Medicine (2005) report, *Food Marketing to Children and Youth: Threat or Opportunity?*, recognizes that dietary patterns begin in childhood and are shaped by the interplay of genetics and biology, culture and values, economics, physical and social environments, and commercial media environments. Importantly, the report provides a

comprehensive review of the scientific evidence on the influence of food marketing on diets and diet-related health of children and youth. It argues that environments supportive of good health require leadership and action from the food, beverage, and restaurant industries; food retailers and trade associations; the entertainment industry and the media; parents and caregivers; schools; and governments.

Global-level regulation of food-related industries, however, remains problematic. The process of adopting the WHO Global Strategy on Diet, Physical Activity and Health was hindered by the food industry's opposition to explicit recommendations on healthy levels of salt, sugar, and fats intake (Lang et al. 2006). In the United States, the powerful food industry has instead succeeded in promoting voluntary and self-regulation. As Kelly (2005) writes:

So far the U.S. government has declined to regulate the aggressive ways in which food producers market high-energy, low-nutrition foods to young people. That public-health responsibility has been left to an industry-created scheme of self-regulation that is deeply flawed; there is a compelling need for government involvement.

Lessons for global health promotion can be drawn from efforts to strengthen tobacco control worldwide. As described earlier, the globalization of the tobacco industry has led to a rise in tobacco consumption, facilitated by the industry's consolidation, greater economies of scale, and aggressive marketing strategies to gain access to emerging markets (Bettcher and Yach 2000). WHO initiated the FCTC in the mid 1990s in recognition of the need to globalize tobacco control policies (Reid 2005). WHO Director-General Gro Harlem Brundtland (2000, p. 2) stated:

[O]ver the past fifteen years, we have seen that modern technology, has limited the effectiveness of national action. Tobacco advertising is beamed into every country via satellite and cable. Developing countries are the subject of massive marketing campaigns by international tobacco companies. In the slipstream of increasing global trade, new markets are opened to international tobacco companies which see these emerging markets as their main opportunity to compensate for stagnant or dwindling markets in many industrialized countries.

The FCTC negotiation process encompassed regional consultations, public hearings, contributions by civil society organizations (CSOs), and old-fashioned diplomacy among member states. The process also faced extensive efforts by the tobacco industry to undermine negotiations through participating on some national delegations, lobbying of tobacco leaf-producing countries and farmers, orchestrating criticism of WHO, and even challenging the science on tobacco and health (Weishaar et al. 2012).

Despite industry opposition, the treaty was signed in 2003 and came into effect in 2005. As of 2012, 176 countries are parties to the treaty. Importantly, the FCTC represents a collective effort across WHO member states to address a clear global public health challenge. The involvement of a broad spectrum of stakeholders, notably CSOs, was critical to raising public awareness and support at the regional, national, and local levels. The mobilization of public health advocates, led by the Framework Convention Alliance, was greatly facilitated by the use of the Internet (focused on the Globalink network) which enabled groups to follow negotiations, organize advocacy activities, and share experiences (Collin et al. 2004). While weaker on some aspects of globalization, such as international trade, than initially hoped, protocols could address

Fig. 1.5.2 Campaign poster for World No Tobacco Day.

other transboundary issues such as smuggling and marketing (e.g. sports sponsorship, Internet sales).

Initiating policies, such as the Global Strategy on Diet, Physical Activity and Health and the FCTC, can raise the profile of health promotion and be effective vehicles for addressing global challenges. The experiences of established campaigns, such as the WHO/UNICEF International Code on the Marketing of Breastmilk Substitutes and Healthy Cities Initiative, and initiatives such as the Public–Private Partnership for Handwashing, show that signing agreements is only a starting point. Implementation requires longer term mobilization of political will, resources, and technical capacity to translate commitments into effective action. Globalization can also be harnessed for health promotion purposes. For example, the tobacco control community has developed campaigns to challenge advertising imagery associating cigarette smoking with glamour and excitement in emerging markets (Fig. 1.5.2). Worldwide consumer boycotts of TNCs, such as Nestlé and McDonalds, have been organized via social media to pressure companies to change

their marketing practices or unhealthy product ranges (Yach and Beaglehole 2003).

In summary, the global spread of unhealthy lifestyles and behaviours pose new challenges for health promotion. In many cases, powerful vested interests within key sectors of the global economy have facilitated this process through foreign investment, production, trade, and marketing practices. There is substantial evidence that these practices are resulting in a sharp increase in NCDs. The public health community faces major challenges in influencing these practices, as well as opportunities to harness aspects of globalization to promote healthier lifestyles and behaviours. Collective action across societies to appropriately regulate the harmful aspects of the global economy remains urgently needed.

Measuring and monitoring the health status of populations

Assessing the health of a given population is the starting point for a wide range of public health activities such as policy reviews,

programme development, goal setting, and resource allocation. There are well-recognized steps for assessing population health status:

- ◆ Define the purpose of the assessment.
- ◆ Define the population concerned and any comparator population.
- ◆ Define the aspects of health to be considered.
- ◆ Identify and review existing data sources.
- ◆ Select the most appropriate existing data (Gentle 2001).

In assessing the linkages between globalization and population health status, two challenges are presented. First, there is variable capacity within and across countries to collect and manage basic health data. Data remains of poor quality or limited availability for many populations as a result. According to WHO (2006b):

A country health information system comprises the multiple sub-systems and data sources that together contribute to generating health information, including vital registration, censuses and surveys, disease surveillance and response, service statistics and health management information, financial data, and resource tracking. The absence of consensus on the relative strengths, usefulness, feasibility, and cost-efficiency of different data collection approaches has resulted in a plethora of separate and often overlapping systems.

To address this problem, the WHO Health Metrics Network (HMN) was formed as a global partnership to strengthen and align health information systems around the world. The partnership is comprised of countries, multilateral and bilateral development agencies, foundations, global health initiatives, and technical experts that aim to increase the availability and use of timely, reliable health information by catalysing the funding and development of core health information systems in developing countries.

A second challenge is the limitations of existing data sources in capturing health needs that cut across the national level. For each country, health data is collected and managed by a department of health and associated institutions. The WHO Statistical Information System (WHOSIS), in turn, collects and coordinates data on core health indicators, mortality and health status, disease statistics, health system statistics, risk factors and health service coverage, and inequities in health from its 194 member states. This is compiled in the *World Health Statistics*. By definition, globalization is eroding, and even transcending, national borders so that health and disease patterns may be emerging that do not conform to such delineations. As a result, national level data may need to be aggregated and disaggregated in novel ways to reveal these new patterns.

A good example is the earlier discussed increase in obesity rates. Improving data on trends in different countries reveal a complex picture. In high-income countries, obesity is rising rapidly across all social classes but is particularly associated with social deprivation. In the United Kingdom, for example:

Obesity is linked to social class, being more common among those in the routine or semi-routine occupational groups than the managerial and professional groups. The link is stronger among women. In 2001, 30 per cent of women in routine occupations were classified as obese compared with 16 per cent in higher managerial and professional occupations. (UK Office of National Statistics Office 2004, pp. 111–12)

In France, Romon et al. (2005) found that genetic predisposition influences the prevalence of obesity and changes in BMI among children from the higher social class. For children within the lowest social class, which has seen an increase in BMI across the whole population, environmental factors appear to have played a more important role. In contrast, in low- and middle-income countries, the total number of obese or overweight people is projected to grow by 50 per cent by 2015 alongside the persistence of undernutrition (Fig. 1.5.3). Social class is one factor. In such diverse countries as Kenya, China, India, and Brazil, obesity among an increasingly affluent middle class has been observed (McLellan 2002). A high BMI may even be considered socially desirable as a sign of affluence. At the same time, some populations within the lower social classes are also experiencing rising rates of overweight and obesity. For example, Monteiro et al. (2004) find that a country's level of wealth is an important factor, with obesity starting to fuel health inequities in the developing world when the GNP reaches a value of about US \$2500 per capita. Trends in over/undernutrition, in other words, are complex and changing over time, and require sufficiently detailed and comparable data across population groups defined along additional variables (e.g. gender, socioeconomic status, occupation).

The need to improve available data on the health of populations affected by globalization is illustrated by a wide range of other examples. The outsourcing of manufacturing to the developing world by TNCs, for example, has led to the employment of hundreds of thousands of workers. What public health needs do these workers have and are they addressed by local occupational health policies? Similarly, the greater movement of people across national borders may require increased attention to the health needs of different types of migrants. Alternatively, what public health issues arise for populations from global environmental change? All of these examples suggest the need to redefine new population groups within a global context, and to develop data sources that measure population health patterns which do not conform to national borders.

The governance of global public health

Governance broadly concerns the agreed actions, rules, and means adopted by a society to promote collective action and solutions in pursuit of common goals. Governance takes place whenever people seek to organize themselves to achieve a shared end through agreed rules, procedures, and institutions. This can take place at different levels of decision-making and action. In public health, if a local community decides to initiate a campaign to slow traffic speed and improve road safety, this requires some form of governance to organize the effort. If a national policy is adopted to improve food labelling and increase the taxation of unhealthy foods, governance is needed to set the agreed labelling standards and rates of taxation, as well as enforce compliance. If a global campaign is initiated to strengthen tuberculosis control, an agreed form of governance is needed to take decisions, for example, on agreed treatment, resource mobilization, and implementation of agreed actions across countries. To what extent is there need for more effective governance to protect and promote public health within an increasingly globalized context?

The existing institutional arrangements for global health cooperation have historical roots dating from the International Sanitary Conferences of the nineteenth century. This series of

Fig. 1.5.3 Per cent of population that is overweight, selected countries, 2002 and 2010 (projected).

Note: 'overweight' is defined as having a body mass index (weight in kilograms divided by height in metres squared) of between 25 and 30. 'Obese' is defined as having a body mass index of 30 or more.

meetings, largely dominated by European countries, focused on protecting trading interests from epidemic diseases such as cholera and plague. The institutions eventually created, such as the *Office International d'Hygiène Publique*, were primarily concerned with collecting and disseminating epidemiological data on these diseases (Fidler 2001). The creation of the WHO as a specialized agency of the United Nations in 1948 was intended to universalize membership, and broaden the scope of, international health cooperation. Its objective, 'the attainment by all peoples of the highest possible level of health', was reflected in the vast array of programmes initiated under WHO's auspices (Lee 2008).

Recent decades have seen challenges to WHO's designated role as 'the directing and co-ordinating authority on international health work' (WHO Constitution, Article 2(a)). In part, this has arisen from differences in perspective on whether WHO should be biomedically (disease) focused, or whether the organization should address the broad social determinants of 'health for all'. These debates have been accompanied by rapid changes in WHO's operating environment, with the ascendance of new institutional players with often competing resources, technical expertise and normative perspectives (McInnes and Lee 2012). From the 1980s, the World Bank became a major influence as the biggest source of financing for health development (Buse 1994), while other UN bodies such as the UN Children's Fund and UN Development Programme (UNDP) expanded their health portfolios. The 1990s saw the creation of numerous global public-private partnerships for health which attracted additional resources, but rendered the policy environment far more complex and crowded (Buse and Walt 2000). In recent years, charitable foundations led by the Bill and Melinda Gates Foundation, have become perhaps the biggest players in the funding of health development (McCoy et al.

2009). This influx of institutions and resources has, on the one hand, reflected the higher priority to health development given by governments, corporations, and CSOs. On the other hand, there is substantial evidence of overlapping mandates, duplication of effort, and, above all, a lack of consensus about how to effectively tackle the collective public health challenges posed by globalization.

The governance of global public health can thus be seen as undergoing a period of transition. In principle, the existing institutions formally responsible for governing public health remain governmental. Public health authority lies within the ministries of health of each WHO member state, and collaboration across countries and regions is expected to take place on a wide range of functions through governmental bodies. However, as described in this chapter, intensified flows of people, other life forms, goods and services, capital, and knowledge are creating transboundary health determinants and outcomes that can transcend state capacity to manage them. This is due, in part, to differences in perspective about what priority goals and actions should be pursued, the capacity of governments to act, and even a willingness to act collectively. Where governments cannot or will not assume a global health governance role, non-state actors in the form of CSOs, charitable foundations, and even corporations have been looked to as potentially filling this governance gap. Many scholars of global governance point to the need for new institutional arrangements to enable more effective action in the face of urgent need. Examples described in this chapter—such as tobacco control, obesity, and infectious disease outbreaks—demonstrate the need for innovation but also the political challenges posed.

What can the public health community do to foster such innovation? Globalization is now an established subject of discussion

and debate at public health meetings around the world, and there has been no shortage of commitments to addressing its impacts. Processes of globalization continue apace and show little signs of reversal. At the same time, the global financial crisis of the early twenty-first century has revealed many weaknesses—the availability of easy credit, incentives to undertake high-risk lending and borrowing, poor fiscal management by governments, and rampant speculative investing. The deep reflection that has accompanied this crisis has included efforts to ‘fix’ the global financial system by creating more effective institutional arrangements that support better global economic governance. There are also opportunities to draw broader lessons. Foremost is a profound understanding of how globalization has tied the fate of billions more closely together than ever before. The debt crises in Europe, for example, have had direct and prolonged consequences for economies worldwide. Problems in the global financial system have profound local consequences for employment, investment, and production. And an ailing world economy has impacts far beyond the financial sector. Public health systems worldwide face both budgetary constraints and increased need amid rising economic hardship within and across countries (WHO 2009). Low- and middle-income countries, especially those dependent on health sector aid, face particular challenges. Since 2009, health sector aid has grown by 4 per cent annually after growing 13 per cent between 2002 and 2008 (Institute of Health Metrics and Evaluation 2011). There are reports that this trend is having direct effects on the ground where aid is used to provide life-saving drugs and treatments not otherwise available (Bennett 2012).

As heads of state, ministers of finance and banking executives ponder over the future of economic globalization, and the need for better checks and balances, how can the public health community play a part in the improved global governance? Public health representation in policy debates on trade and finance to date has been limited yet, for the earlier given reasons, increasingly critical. WHO and other public health institutions have remained marginal observers in the WTO and other key decision-making forums. The controversy surrounding intellectual property rights and access to medicines, the substantial concern by consumers about the social and environmental harms of globalization, the looming economic time bomb of NCDs, and the potential costs to the world economy of a lethal infectious disease pandemic demonstrate the scope for greater collaboration across sectors. The global public goods for health approach, for example, addresses globalization and health from an economic perspective. The concept identifies where a good or service (such as knowledge of an infectious disease outbreak), which would be of benefit globally, will not be produced or disseminated if left to the market because no one can be excluded from accessing the good, and thus no charge can be levied for its use and no costs recouped. There may even be economic disincentives to produce certain goods, such as outbreak reports, because of resultant negative economic consequences. At the national level, the production of these goods is usually ensured by government intervention, but at the global level there remains no ‘global government’ to undertake this role. Certain functions of public health may be classed as global public goods (e.g. immunization programmes, disease surveillance), which require collective action to overcome market failures (Smith et al. 2005). The concept might thus be an appealing rationale to non-health policymakers shaping global change. The potential role of health

impact assessment for informing non-health policy proposals is another such approach (Lee et al. 2007). Most importantly, the long-term sustainability of globalization requires public health to be a core part of any efforts to build better global governance.

Conclusion

This chapter has described key ways in which globalization is relevant to the theory and practice of public health. There are both threats and opportunities arising from the complex and diverse changes created by globalization, although current forms of globalization are clearly characterized by an inequitable distribution of winners and losers. For the public health community, there is a need to understand and contribute to more effective management of the rapid changes taking place. Greater attention to these public health impacts will, in turn, contribute to more sustainable forms of globalization.

Determinants of health: overview

Justin V. Remais and Richard J. Jackson

Introduction to determinants of health

The determinants of health are classically categorized into behavioural factors, impacts of the natural environment, genetic determinants, and social determinants, but these overarching categories mask the complexity and diversity of, and interaction between, the drivers of health and disease. These fundamental determinants have acted, and interacted, within populations in complex ways throughout history. For example, the European conquest of the Americas in the sixteenth century decimated native American populations not just through subjugation (social determinants), but also through land confiscation and associated food insecurity (social and environmental determinants), and the spread of infectious diseases—smallpox, measles and plague among them—that Europeans had developed moderate resistance to over generations (biological determinants) (Brooks 1993; Eyles 2003). More nuanced views of the determinants of population health include disease prevention efforts and medical interventions, as well as genetic predispositions to disease and immunological naiveté. Spanning the fundamental determinants are the additional issues of population dynamics, and political and cultural factors, which can have a wide range of impacts both health promoting and health damaging.

Specific cultural practices, for instance, can make a population more or less susceptible to disease. The wiping of an infant's umbilical cord with dung can raise the risk of tetanus and other infections (World Health Organization 1999), while use of lead-containing pigments in cosmetics and medicaments can lead to anaemia, nerve damage, and other disorders (Al-Saleh et al. 2009). Conversely, breastfeeding is a cultural practice that is health protective, reducing the risk of diarrhoeal infections and death among infants in particular (Smith et al. 1973). Meanwhile, tobacco use and tobacco restriction are other examples where cultural practices exert strong influences on population health and well-being, and an improved cultural understanding of tobacco use can provide new opportunities for changing smoking behaviour and approaches to tobacco control (Nichter 2003; Unger et al. 2003).

Similarly, economic conditions are major determinants of health. Countries that experienced increasing prosperity during the twentieth century achieved better housing, reduced crowding, improved water and food quality, and reduced dangerous working conditions (Kangas 2010). These improvements have contributed to reduced rates of a multitude of diseases—e.g.

diarrhoea, tuberculosis (TB), occupational respiratory diseases—and have led to dramatically increased lifespan and better health (Kjellstrom and Mercado 2008). Yet as the twentieth century progressed, certain aspects of increased affluence led to new population health risks, such as increased consumption of calories and salt. The abundance of relatively inexpensive processed foods high in sugar, fat, and salt has been associated with epidemics of obesity, diabetes, and other chronic diseases across most of the wealthier nations, as well as in the rising middle class in certain low- and middle-income countries (LMICs) (McLellan 2002; Remais et al. 2013). At the other end of the economic spectrum, poverty and resource limitations are associated with unhealthy housing, deficient infrastructure, malnutrition, and dangerous sweatshop working conditions.

As economic conditions improve, opportunities arise to invest in relatively inexpensive and widely distributed public health interventions. Examples include the provision and disinfection of water supplies, or the fortification of foodstuffs—flour and other grain products being most common—with micronutrients (Backstrand 2002; Thompson et al. 2003). Similarly, reduction in unventilated cooking with solid fuels in the home can reduce the risk of severe respiratory disease (Smith et al. 2011), while chemicals can be regulated to reduce exposures, and vehicular and building safety codes enacted and enforced. The impact of such basic measures to protect health can be tremendous: a magnitude 7.0 earthquake in 2010 in Haiti resulted in over 200,000 deaths, while a much larger earthquake in Chile that same year resulted in the loss of 700 lives (Harrell 2010). While there is a range of economic, social, political, and resource differences between the two countries, the fundamental importance of the establishment and enforcement of building codes was made apparent in these two tragic disaster contexts.

As our understanding of the determinants of health has expanded, the catalogue of determinants has grown as well, as has appreciation for their interaction at individual and population levels. Distal, far-reaching drivers of health and disease have recently been acknowledged as central determinants of public health. Globalization, climate change, and urbanization, for example, are receiving increasing attention as complex socioenvironmental phenomena—linked to health though rapidly shifting pathways—that fit poorly into the classical categorizations (McMichael 2000; McMichael and Campbell-Lendrum 2003; Gong et al. 2012). To address the key public health challenges and capacities of the

twenty-first century, the catalogue of determinants will need to expand further, but their interactions must also be understood and acted upon. For instance, the convergence of infectious and non-communicable diseases in rapidly changing settings like India reflects the dynamic interplay between diverse health determinants (Remais et al. 2013), requiring a synthetic and comprehensive approach to health determinants, as well as new approaches to research and public health response. In this chapter, we discuss several such complicating features of the determinants of health, addressing the challenges they raise for public health institutions, professionals, and the policies and interventions they develop and deploy.

We describe how the temporal characteristics of health determinants—their dynamism—introduces complex delays and feedbacks, issues related to cumulative exposures, and raises the need for a life-course perspective and a lasting commitment to longitudinal studies, and long time-horizons for policy analysis. We explore how the multiple scales of health determinants—from molecular to global, distal to proximal—will require cross-sector and cross-disciplinary science, and new technologies for studying, interpreting, and acting on multi-scale health challenges. The cross-boundary nature of the determinants of health are discussed, including the movement of people, policies, capital, and pollutants inherent in global migration, trade, finance, and the transport of transboundary pollutants. Finally, we discuss the influence of abrupt state changes, such as those brought about by conflict or disasters, on health, addressing the need for leadership that is robust to, and prepared for, change, as well as policies that enhance resilience.

Complicating features of determinants

Dynamism

The determinants of health are complicated by their dynamism. The common practice of expressing the relationship between exposure and disease as a relative risk does little to convey the complexities of the temporal relationship between exposure and disease. An abrupt change in exposure, for instance, may not lead to a sudden change in the associated disease response. Time lags between exposure and disease, or disease responses for which cumulative exposures are required, have posed significant challenges to improving our understanding of important health risks, such as indoor air pollution and cancer risk assessment. Health-damaging exposures themselves have complex temporal characteristics, with specific time-scales relevant to particular health outcomes—i.e. cumulative long-term levels are most relevant to some exposures, peak levels most relevant to others.

These exposures are experienced over a series of life stages, and factors influencing growth and development early in life can have dramatic consequences for health in adulthood. A life-course perspective highlights the importance of considering the dynamic nature of health outcomes, as insults during fetal, infant, and childhood development—such as those stemming from maternal and childhood undernutrition, childhood infections, and certain environmental exposures—can lead to susceptibility to multiple health outcomes later in life (Cohen et al. 2004; Gluckman et al. 2008; Chan et al. 2009; Dowd et al. 2009; Winans et al. 2011). Inadequate development of the human body early in life, which is prevalent in LMICs, can impede vitality and

ultimately longevity. There is increasing evidence that certain *in utero* and early-life conditions individuals and populations can lead to both infectious and non-communicable chronic diseases later in life (Gluckman et al. 2008; Rinaudo and Wang 2012; Remais et al. 2013).

The dynamism of the determinants of health raises methodological challenges when carrying out research to clarify the relationship between time-varying exposures and outcomes. Methods are needed to contend with dynamism, for instance by accounting for the timing of exposure and resulting disease, and applying analytical approaches to adjust for effects experienced in the future, such as discounting. Such approaches must reconcile tricky issues related to the relative importance of current versus future conditions when little consensus exists as to which discount rates are best used in such analyses (Weitzman 2001). This poses special challenges for assessing the health impacts of exposures that extend far into the future (e.g. those associated with global climate change), as well as policies and interventions that are phased in over decades (e.g. smoking cessation campaigns). Indeed, dynamism introduces major policy challenges weighing the relative importance of experiencing a given outcome in the present versus the future, forcing the public health community to strike an explicit balance between the interests of current and future generations.

Addressing the dynamic characteristics of the determinants of health will require a commitment to addressing these difficult estimation, valuation, and policy issues, including longitudinal studies with tailored designs that capture the time-course of complex exposures and outcomes. Research designs that span the life-course are one example, as are approaches to account for the diverse time-course of health interventions. Likewise, long time horizons for policy analysis are needed in order to account for long-term impacts that may be overlooked in near-term analyses, such as those that stem from changes to diet and nutrition. These temporal issues, which complicate the timing of exposure and disease as well as our ability to study and respond to them, combine with the challenges associated with health determinants that are multi-scale.

Multi-scale

The determinants of health are not only dynamic and changing, they operate at various scales. Persons who are charged with promoting health—both directly and indirectly—typically operate at the scale of their training. Physicians and nurses work at a personal scale, hospital administrators and health product manufacturers at a more derivative scale, ministers of health at a focused governance level, and at the top level, elected (or arrogating) officials develop and execute military, industrial, agricultural or other policies with sweeping and sometimes global consequences for health. Indeed, at this level national and international leaders frequently make decisions that have great influence on health with limited awareness or consideration of impacts on health. It is the role of health officials to assure that political and institutional leaders at all levels understand health determinants, which themselves span a wide range of scales and domains. Solutions to interconnected challenges, for example, prevention of waste or contamination of drinking water, can offer benefits across not just health domains, but benefits for food and industrial production, cost, and environmental savings (Hanjra et al. 2012).

Virtually all health challenges span scales ranging from the molecular to the microscopic to the global. For example, transmission of *Plasmodium* spp. malaria parasites is regulated by host factors (e.g. immunological, nutritional, etc.), by the local population prevalence and dynamics of mosquito vectors, and by global factors such as climate change that can influence the parasite's spread across regions and continents (Pascual and Bouma 2009; Moore et al. 2012; Dhingra et al. 2013). These scales are not equally valued by health practitioners, who may, for instance, consult with immunologists and microbiologists about the first and second scales, and neglect the latter. Management of multi-scale issues requires that practitioners understand the range of parameters, from microbiological to climatological, that drive such health threats, often requiring them to identify the limits of their expertise, and to articulate the need to abate large-scale determinants, not merely the narrow ones. The spread of malaria is influenced by actions at the personal, community, and governmental levels, which together determine housing infrastructure, availability of bednets, types of livestock, degree and extent of mosquito abatement, insecticide resistance, heat island effects, cost of diagnosis and treatment, and other factors. Managing multi-scale challenges requires cross-domain awareness, technical training, analytical skills, and practical experience.

Cross-boundary

Many key public health threats pose risks that transcend international borders, such as risks resulting from mobile atmospheric or aquatic environmental pollutants, and those that stem from global socioeconomic integration (e.g. increases in global air transport, trade, and migration). In the former category, air pollutants, for instance, are transported internationally and intercontinentally (Zhang et al. 2008; J. Liu et al. 2009), and the consequences for public health thus extend far from the site of emissions. Dust from sources in Asia traverses the Pacific and has reached surface locations in the United States in a matter of days (Husar et al. 2001), and mercury emitted mainly from coal combustion remains in the atmosphere for about a year and poses a serious cross-boundary threat (Selin 2005). Likewise, greenhouse gases (e.g. carbon dioxide and methane) lead to global climate change no matter where emissions occur, and thus the health and economic consequences, such as loss of life and property resulting from increased frequency of extreme temperature events, are widely dispersed across national and continental boundaries (Zhang et al. 2010).

Meanwhile, tighter global economic integration has important public health consequences that are in the early stages of comprehension. For instance, biofuel energy policies in established market economies can have a nutritional impact in developing countries when a portion of global agricultural production is switched to biofuel feedstocks. The macroeconomic effects of such a switch can yield rapid changes in prices of global food staples (Chakravorty et al. 2009), such as occurred in 2007 when average global grain prices rapidly increased in part as a consequence of the expansion of biofuels to meet national blending targets in the European Union, United States, and other countries (Mitchell 2008; Rosegrant 2008). Increases in food prices, and other economic shocks, can have major consequences for undernutrition (Friel et al. 2009; Bloem et al. 2010), yet large uncertainties remain in our understanding of the complex factors that link global economic integration and

public health, such as those that drive global food prices (Mitchell 2008) and determine regional resilience to price spikes (Webb 2010) in this example.

Responding to these and other transboundary risks requires coordination of policy goals and regulations between diverse governments, increasingly involving a range of public and private actors at various policy levels (Winter 2006). The World Health Organization and other multilateral institutions can play a key role in coordinating policies to confront transboundary risks, and in facilitating uptake of interventions that are tailored to national and regional needs. International scientific collaboration has been essential to the characterization of the health risks of global climate change and stratospheric ozone depletion, and policy measures that sustain such interactions are needed, such as open-access publication and data sharing requirements, coupled with open-government transparency initiatives that make essential data public. Besides transcending boundaries, certain health determinants are characterized by abrupt shifts, raising additional challenges.

State changes

Large, abrupt changes at societal or planetary levels can drive patterns of health and illness, often for generations. Conflicts between nation states often originate from resource competition, although camouflaged as moral, religious, or ethnic disputes, and can affect health not just for years but for generations (Klare et al. 2011). Wars fought over land and water rights, for instance, can exact heavy and rapid health and economic tolls, and can arise even among seemingly similar religious or ethnic groups, such as Protestants and Catholics in Europe, or the Tutsi and Hutu in Africa. National conflicts can cause abrupt tears in the social fabric, including scores of civilian casualties, the loss of homes and community support systems, sudden depletion or loss of food, water, and other essential resources, and large, rapid unplanned migrations of populations under dangerous conditions. Mental health consequences invariably accompany these abrupt changes to systems that support health (Murthy and Lakshminarayana 2006), and when a new stable state is achieved, it can often be far inferior in its support of population health, such as the establishment of long-term refugee camps, forced repatriation, or loss of nationhood accompanied by ongoing social unrest.

Strategies, diplomatic and technological, to mitigate the flash points for conflict will be necessary, and such strategies must be included in the domain of the health professions. While it may seem a truism that state conflict is a powerful determinant of ill health, health leaders have often shied away from confronting and addressing such threats. In 1985, the Nobel Committee awarded its Peace Prize to International Physicians for the Prevention of Nuclear War, validating the work of health professionals confronting the threats of nuclear war, and elevating the role of health leaders in preventing abrupt state changes to the systems that support health, and minimizing the devastation, health and otherwise, that follows conflict. When conflicts do occur, the important roles of the Red Cross, Red Crescent, and other voluntary health organizations are critical. Large-scale movements of displaced persons give rise to highly vulnerable populations—for example, children and the elderly—placed in circumstances directly hazardous to health and prone to epidemics. Provision of fundamental public health

services in such settings is essential, yet as in most circumstances, never as effective as prevention of the conditions that brought on displacement in the first place.

Besides being a source of conflict, resource depletion can itself directly cause abrupt state changes to key earth systems that support health (Tong 2000). These can be brought on by increasing population, emissions of greenhouse gases, and depletion of fresh water, arable land, and other essential resources. A major challenge is that climate change and other global shifts with large consequences for health are often seen as slow moving threats, perhaps best dealt with at some later date. Evolving threats, such as the gradual increase in surface temperatures across the planet, are punctuated by abrupt state changes as well, for example, increased frequency of extreme weather events, which can generate immediate and large health crises. Perhaps the most dramatic example of this is the 2005 heat wave in Europe that caused over 40,000 deaths as a consequence of lasting, dangerous heat conditions that transpired more rapidly than the public health response could mitigate. Such weather extremes, stemming from steady changes in climate, are an inevitable consequence of unmitigated emissions of greenhouse gases, though impacts are difficult to precisely attribute. Avoiding large, irreversible negative health outcomes from abrupt state changes brought on by poor energy, agricultural, and other national policies demands rigorous analysis and leadership from the health sector.

Examples of determinants exhibiting such complexity

Interactions between migration, healthcare delivery, and immunization: an example in China

A range of determinants illustrates the complications described earlier, and among them global urbanization serves as an especially illuminating example. Urbanization is proceeding at rapid pace globally, presenting substantial health risks, such as the challenges of meeting the healthcare needs of large, migrating populations. Urbanization impacts health through complex and multifactorial pathways, involving a number of the complications already described. In China, for instance, the health risks of urbanization are not borne equally: the major healthcare delivery challenges that arise from rapid rural-to-urban migration have diverse impacts on migrant populations. Provision of childhood immunization services to the children of migrants, for example, has been significantly complicated by urbanization (Gong et al. 2012). The country established extensive programmes in the early 1970s to provide basic childhood vaccines—e.g. TB, diphtheria, pertussis, tetanus, polio, measles, and more recently hepatitis B (HBV)—and since 2005 has offered nine vaccines to all neonates and infants nationwide without regard to ability to pay. Coverage has increased dramatically in rural areas, e.g. for HBV from less than 50 per cent in 1993 to greater than 80 per cent by 2006 (Zeng et al. 1998; Cui et al. 2007).

Having dramatically reduced the urban–rural gap in coverage is a major accomplishment for China, yet the country’s mass rural-to-urban migration phenomenon has generated a new trend: immunization coverage among the children of migrants is now lower than that of both urban and rural children (Zeng et al. 1998; Cui et al. 2007; Lin et al. 2007, 2011; Liu et al. 2007;

Qin et al. 2007; Zhou et al. 2008). Thus, an urban–rural gap in immunization coverage has given way to a gap between migrant and non-migrant populations, and this problem has been compounded by the unprecedented, dynamic timeline of the country’s migration phenomenon. The country’s migrant population has risen to more than 260 million, up from 98 million in 2004 (NBSC 2011), and urbanization equivalent to the scale of China’s experience over the past few decades was accomplished over hundreds of years in the West. The extraordinary pace of change has produced complex interactions between migration, healthcare delivery, and immunization, but has also driven trends in other key health determinants for migrant populations, such as dangerous working and living conditions, income inequality, and psychological stressors (Gong et al. 2012). Strengthening health programmes to reach migrant populations must be made a high priority for rapidly urbanizing countries, yet a better understanding of the complex pathways linking urbanization to health is urgently needed. Characterizing the causal web will require a multidisciplinary research approach, as well as a commitment to longitudinal studies capable of quantifying the long-term impacts of the transition from rural to urban living in a way that captures both health opportunities and risks (Gong et al. 2012).

Interactions between determinants of infectious disease and of non-communicable chronic disease

Another key example where the determinants of health are interacting in novel ways is the convergence of non-communicable disease (NCD) and infectious disease (ID) in LMICs—a convergence that existing health systems and public health approaches must grapple with. Prevention and control programmes for NCDs—like cardiovascular disease and diabetes mellitus—and IDs—such as TB, HIV/AIDS, and certain parasitic diseases—rarely interact, even though NCDs and IDs share important common features. There are common risk factors for NCDs and IDs, and key interactions between NCDs and IDs lead some individuals with NCDs to be more susceptible to IDs. For example, diabetes increases susceptibility to various communicable diseases, such as TB and malaria. As a result, LMICs are experiencing a large, simultaneous burden of disease from NCDs and IDs (Remais et al. 2013). Diabetes in India, for instance, is estimated to be responsible for more than 10 per cent of the country’s 2 million annual TB cases (Ruslami et al. 2010). Diabetes prevalence is projected to increase in India, and as a result the proportion of TB cases attributable to diabetes is projected to increase as well (Ruslami et al. 2010). These interactions between two categories of diseases historically separated by deep professional divides will necessitate new collaborations between NCD and ID researchers and between NCD and ID programme leadership (Remais et al. 2013).

Fundamental data on ID and NCD co-morbidity in LMIC populations must be collected to understand their overlap in populations (Ebrahim et al. 2013), and public health services must be targeted to reach populations found to be exposed to common ID and NCD risk factors, and provide for their healthcare needs. Importantly, the presentation of comorbid NCDs will likely pose new complications to treating IDs, and vice versa, in ways not yet fully explored (Remais et al. 2013). Clinical vigilance will be called for, and as new information emerges, screening and treatment programmes will have to efficiently adapt. Although the convergence of NCD and ID stems from a well-understood risk

overlap that drives epidemiological transitions (Smith and Ezzati 2005), the phenomenon presents challenges to the historic divisions in the public health professions, such as the partitioning of chronic and infectious disease epidemiology (Barrett-Connor 1979; Remais et al. 2013). These will need to be overcome if the necessary changes in policy and research are to be enacted, and new approaches to prevention that acknowledge common determinants of NCD and ID, particularly those outside the health sector, will be crucial to doing so (Yang et al. 2008; Gong et al. 2012; Remais and Eisenberg 2012).

Environmental health versus economic development and inequality

Historically, the early stages of national economic development begin with resource extraction and resource-rich developing countries are often courted by industrial countries and their multinationals for access to their raw materials, along with their inexpensive labour, weak environmental regulations, and sites for hazardous waste disposal. These industries can generate rapid wealth, and the political and financial conditions that accompany extraction economies run the risk of becoming repressive toward labour rights, and indifferent and hostile to environmental protections (Reed 2002). What is more, extraction and commodity industries are often subject to ‘boom and bust’ cycles, which can be detrimental to social stability and health. Maintaining good governance in the face of an influx of new wealth, generated by a small number of industrial agents, can be challenging, and political processes have been observed to be manipulated by vested interests (Hilson and Maconachie 2008). Weak governance during boom-bust cycles can render public services such as schools, transportation, and healthcare ineffective and at times non-existent.

Understanding and addressing issues of environmental health and economic development is essential for ensuring that cycles of resource extraction, political corruption, environmental pollution, and occupational illness are avoided, and examples of successful and environmentally sustainable industrial development are broadly adopted. For example, while extraction of precious metals can present grave risks for miners and smelter workers—for example, gold miners exposed to toxic cyanide or mercury, or diamond miners working in extremely hazardous pits—mining practices have been developed that protect worker health, reduce environmental pollution and are economically viable (Amezaga et al. 2011). Historically, the health sector has argued persuasively for expansive policies to address industrial pollution, urging that societal response should extend beyond the clinical setting (e.g. treating an individual poisoned by metals pollution) into the environment where exposures were taking place (e.g. preventing exposures before they occur) (Remais and Eisenberg 2012). Public health leaders will need to resuscitate this historical role, insisting that funding priorities, research, and policies ensure that sustainable industrial development be implemented based on the best evidence and experience to date.

Ageing and urbanization

Ageing and urbanization are occurring simultaneously in many settings, raising unique public health challenges and illustrating the dynamic, multi-scale nature of the global determinants of health. China, for instance, is experiencing a demographic age shift as a result of declining fertility and increasing life expectancies

(Lutz et al. 2008). Fertility has declined nearly 70 per cent since 1950 (Chen and Liu 2009) and life expectancy reached 73 years in 2005 (Zeng 2009). Accordingly, the proportion of China’s population 65 years of age and above is projected to reach 25 per cent by 2050, up from 7.6 per cent in 2005 (Flaherty et al. 2007; Chen and Liu 2009). The health determinants unique to ageing populations are interacting with those that accompany the urbanization experience described earlier. China’s urban populations have lower fertility and longer life expectancy on balance (Zeng and Vaupel 1989; Li and Tan 2011), which thus tends to yield rapidly ageing urban populations. At the same time, however, tens of millions of migrants, most of whom are young (Wang 2008; Yeh et al. 2011), have flowed into urban areas in China, counterbalancing the tendency of ageing in urban settings. Meanwhile, as a result of the same flux of youth into urban centres, rural areas are ageing very rapidly, raising unique public health issues in these settings (Gong et al. 2012).

For instance, the children left behind when working-age adults leave rural areas—20 million such children are estimated throughout China (Duan and Zhou 2005)—may be at greater risk of injury in part because of reduced supervision of young children under the care of a single parent (Shen et al. 2009). Deleterious mental health effects have also been observed in this so-called ‘left-behind’ population (Z. Liu et al. 2009). At the same time, the rural elderly population is becoming increasingly dependent on familial support, rather than pensions or social security, for their income (Wang 2006), and mass migration has had the dual effect of both increasing the geographic distance between adult children and their parents (Joseph and Phillips 1999; Chen and Liu 2009) and also providing job opportunities in cities that can increase financial transfers from adult children to their parents (Giles et al. 2010). Addressing the public health effects of these complex interactions between urbanization and population ageing will require approaches and policies that differ from traditional modes of strengthening social security. Expanding support networks for rural elders in the absence of familial ties may be one such approach, as well as injury prevention programmes aimed specifically at reducing accidents among children under the care of single parents, or grandparents, in rural areas. Development of such initiatives will require interaction between a range of social programmes, healthcare systems, and pension schemes, and such efforts are steadily gaining support in China and elsewhere (Gong et al. 2012).

Health risks and benefits of urbanization

No major social, environmental, or behavioural change is without health impacts, both positive and negative, and examining the benefits, alongside health risks, is essential. Returning to urbanization, the phenomenon in LMICs is frequently characterized as essential to future prosperity, while at the same time a threat to health and, in the case of unplanned urban expansion and sprawl, harmful to local and global environmental quality. Globally, migrant flows are continuing into cities at a rapid pace, and important adverse health effects that have long been associated with living in urban areas have been extensively reviewed (e.g. Whiting and Unwin 2009; Gong et al. 2012), some of which have already been discussed.

Notable adverse health impacts include transmission of infectious diseases, such as TB and HIV, facilitated by increased

density and mobility of populations, especially within urban slums (Alirol et al. 2011); obesity and diabetes linked to sedentary urban lifestyles and greater access to fatty and sweetened processed foods in urban areas (Ford and Mokdad 2008; Townshend and Lake 2009); and malaria, dengue, and other diseases carried by vectors that capitalize on urban landscapes with poor management of water resources and high host population densities (Keiser et al. 2004). Urban environments are associated with a breakdown of traditional support networks, decreasing social capital and increasing susceptibility to stress, mental illness, and violent crime (Galea et al. 2011). These adverse health effects have been found to vary between countries, among cities in the same country, and within cities (Ompad et al. 2007), and the urban poor disproportionately experience the burden of these ill effects (Kjellstrom and Mercado 2008). In fact, in some instances the urban poor can suffer greater morbidity and mortality from infectious diseases than the rural poor, an indication of the substandard living conditions and poor services in some urban areas, such as a near-complete lack of sanitation facilities and a wide variety of barriers to accessing health services in cities (Satterthwaite 2011).

Conversely, a number of possible health benefits accrue to urban populations, many of which may be unique to urban areas. Greater access to improved water and sanitation facilities, health-care infrastructure, and nutritional opportunities are examples (Bissonnette et al. 2012), and with decades of rapid urbanization ahead for most LMICs, a comprehensive characterization of the health benefits is needed, alongside extensive research on adverse effects. An analysis of both the health risks and benefits of urbanization can help in the development of strategies to alleviate the ills of urban living, while maximizing the health benefits urban settings offer. Importantly, examining the mechanisms by which urban areas may lead to health gains will be essential, including those that flow from the main distinguishing characteristics of urban areas: high population density, concentration of infrastructure, and rapid social and environmental change. In a future public health environment where political leaders need access to the best evidence to inform policies ranging from industrial to banking, agricultural to social, transportation to health, it will be essential to fully characterize health benefits of policies alongside their adverse impacts.

Conclusion

Addressing the public health challenges of the twenty-first century will require new approaches to understanding, quantifying, and responding to complex, dynamic health determinants. Interactions between health determinants at multiple scales will need to be understood and acted upon, departing from traditions among healthcare providers to consider, and act at, only scales within their training. The cross-boundary nature of health determinants, highlighted by rapid trends in the international movement of people, policies, capital, and pollutants, must be addressed through new global policy mechanisms. There will be a need for global leadership from the health sector to address these major challenges, both from within public health institutions, as well as within other private and public sector institutions setting a range of global policies that influence health through both direct and indirect pathways.

Poverty, justice, and health

Ronald Labonté, Frances Baum,
and David Sanders

Introduction to poverty, justice, and health

Poverty has to be understood not just as a disadvantaged and insecure economic *condition*, but also as a shameful and corrosive social *relation*. (p. 7, emphasis in original)

Reproduced from Lister, R., *Poverty*, Polity Press, Copyright © 2004.

Poverty has long been a concern in public health. Not only do the poor generally suffer higher burdens of disease, but during periods of infectious epidemics or pandemics they are perceived as posing a risk to the non-poor as well. Recent studies even suggest that high poverty and disease rates together can contribute to social unrest and ‘failed’ (or failing) states (Cheek 2001; Hotez 2002; Singer 2002; Peterson and Shellman 2006). Apart from these more ‘public’ (or population) health risks, the persistence of poverty has also led many public health theorists and practitioners to ask why poverty continues to exist in times of great global wealth, and to argue that a socially just society would seek to eliminate poverty. The reasons for the persistence of poverty lie in how societies’ economic and political systems allocate the opportunities and resources people need to be ‘non-poor’ and healthy, or intervene to reduce inequities (avoidable inequalities) in their access to services and resources. Thus, any discussion of poverty, and of its impacts on health, unavoidably intersects with understanding how inequalities arise in the distribution of income and wealth, and of the material and psychosocial resources these socioeconomic privileges accord. As the British economist-cum-philosopher, Adam Smith, known best for his writings extolling the virtues of free markets, noted:

Wherever there is great property, there is great inequality. For one very rich man, there must be at least five hundred poor, and the affluence of the few supposes the indigence of the many. (Smith 1776, p. 419)

But what exactly is poverty? How is it affecting health, and ill health affecting poverty? And what theories or practices of justice should guide public health interventions based on poverty’s persisting health risks? These three questions form the basis of the chapter that follows.

What is poverty?

At first glance, it may seem simple to define poverty: the inability of people to provide for the basic necessities of life. But there are actually many forms of poverty, all of them important to public health and to public policy; and the concept of poverty itself is ‘highly

contested’ (Alcock 1993, p. x). Its contestation is not simply theoretical (what does it mean?) or empirical (how do we measure it?) but also political, since it is the same sociopolitical structures and economic arrangements that give rise to both poverty and affluence.

Absolute poverty

There are people in the world so hungry, that God cannot appear to them except in the form of bread.

Mahatma Gandhi, reproduced with permission from the Nanajivan Trust.

Absolute poverty is foundational to an understanding of the concept, and is commonly considered to be the lack of a minimum income necessary for simple survival based upon the price of a basket of ‘essential’ goods and services (Masters and Wickstrom 2006; Saunders et al. 2008). The World Bank has standardized poverty measures globally through its ‘dollar a day’ and ‘two dollars a day’ poverty rates. The dollar-a-day level, close to the national poverty line in India, has since been raised to \$1.25/day as a more common metric, a figure that represents the average national poverty line of the poorest 10–20 countries (Chen and Ravallion 2012). The two-dollar-a-day level is the median national poverty line for all developing countries. Dollar-a-day poverty describes subsistence consumption at a level that is minimally life-supporting and ‘exceptionally frugal...even by the standards of the world’s poorest countries’ (Chen and Ravallion 2012, p. 1). Raising this to \$1.25/day does little to improve the material circumstances of those who live on it. Two-dollar-a-day poverty describes consumption that accommodates other essential basic needs such as land, agricultural tools, and some access to education and healthcare, although it remains associated with comparatively low life expectancies and high infant and maternal mortality rates. (We discuss the relationship between poverty and health later in this chapter.)

Global poverty rates at all three levels (\$1, \$1.25, and \$2/day) have continued to fall since the baseline year of 1981 (Table 2.2.1), often attributed to globalization-associated economic growth (Santarelli and Figni 2002; World Bank 2002). The absolute number of people worldwide who are living below these levels has also fallen, but there are important regional variations. Poverty rates and absolute numbers fell most dramatically in East Asia and China. Poverty rates and absolute numbers rose in Latin America and the Caribbean during the 1980s and 1990s—the ‘lost decades’ that many attribute to structural adjustment programmes imposed by the World Bank and International Monetary Fund (Grindle 1996)—before beginning to

Table 2.2.1 Percentage and number of people in the developing world living below World Bank poverty levels, 1981 and 2008

Poverty level	1981 percentage	1981 number	2008 percentage	2008 number
\$1/day	42	1.54 billion	14	801 million
\$1.25/day	52	1.94 billion	22	1.29 billion
\$2/day	70	2.59 billion	43	2.47 billion

fall in the 2000s. The recent decline in poverty in this region is a result of economic growth combined with redistributive social policies and programmes (Birdsall et al. 2011). Poverty rates in sub-Saharan Africa fell only very slightly over this 30-year period, and failed completely to keep pace with population growth as the continuing rise in number of poor indicates (Fig. 2.2.1). Globally, there were only modest gains in decreasing poverty at the two-dollar-a-day level, and a substantial rise in the number subsisting between the \$1.25 and \$2/day rates, which 'points to the fact that a great many people remain vulnerable' (Chen and Ravallion 2012, p. 3).

**Fig. 2.2.1** Proportion of population and number of people living in poverty in sub-Saharan Africa between 1981 and 2008.

Source: data from Shaohua Chen and Martin Ravallion, *An update to the World Bank's estimates of consumption poverty in the developing world*, Briefing Note 03-01-12, Development Research Group, World Bank, Copyright © 2012.

These data mean that the not very ambitious Millennium Development Goal of halving the number of people living in extreme poverty (\$1 or \$1.25/day) between 1990 and 2015 has been achieved. Of comparative significance is that the value of the global economy more than quadrupled during this same time period—from US \$18 trillion in 1980 (De Long 1998) to US \$80 trillion in 2011 (Central Intelligence Agency 2013), indicative that very little 'trickle down' of the benefits of that growth reached the 'bottom billion' (Collier 2007). Neither does halving these rates say anything of the adequacy of the poverty lines themselves, to which other analysts have responded with estimates of an 'ethical poverty line'. The ethical poverty line was established by working backwards from countries with an average life expectancy at birth of 74 years (considered an ethical minimum) to the average level of consumption associated with such a life expectancy (around \$3/day) (Edward 2006). Using this \$3/day poverty line increases the number of global poor by 1.3 billion to around 3.7 billion, or roughly half the planet's total population. By one estimate, which assumes a continuation of global economic growth and poverty reduction rates of the past two decades, cutting 'ethical poverty' by half would take between 116 and 209 years (Woodward and Simms 2006), would still leave half the world behind, would achieve life expectancies for those above the ethical poverty line a decade less than that enjoyed by wealthier people in high-income countries, and would almost certainly destroy the ecological resources required for life long before achieving this effect.

Finally, the World Bank's estimates of people living in absolute poverty are generally based on what people report consuming. Since many of the world's poor consume healthcare for which they have to pay, this can result in *medical poverty*, when catastrophic illness forces people to sell their assets and exhaust their savings to pay for treatment. These people may lift themselves out of 'consumption' poverty (since they are consuming healthcare at a high level) but leave themselves in income poverty (since they no longer have money for other goods or services). In 2005, the World Health Organization (WHO) estimated that:

Each year 100 million people slide into poverty as a result of medical care payments. Another 150 million people are forced to spend nearly half their incomes on medical expenses. That is because in many countries people have no access to social health protection — affordable health insurance or government-funded health services. (WHO 2005)

Recognizing the seriousness of medical poverty, in December 2012, the United Nations General Assembly passed a resolution calling on Member States to develop universal health coverage systems to prevent significant payments at the point of delivery and to pool risks to avoid catastrophic healthcare spending and impoverishment (United Nations General Assembly 2012).

Absolute poverty informs public health by way of a presumption that people living at or below such poverty lines lack access to sufficient material resources to develop or maintain their health. Apart from the ethical poverty line, this level of poverty represents a form more commonly associated with poor groups in low-income and middle-income countries than with poor groups in high-income countries. This poverty concept nonetheless applies to high-income countries where some households live in 'deep poverty', where income levels are 75 per cent or less of nationally established poverty lines and are considered inadequate to meet even basic needs of food, shelter, and clothing (Beiser et al. 2002).

Conservative think-tanks in high-income countries have sometimes argued that absolute poverty, which is indifferent to measures of income or wealth distribution, should be the only policy concern. Not all agree. Apart from growth-related poverty reduction being much less under conditions of high income-inequality (Bourguignon 2004), most of the world's absolute poor now live in middle-income countries such as India and China, making governance, taxation, and redistribution of paramount importance in reducing levels of absolute poverty (Sumner 2010).

Relative poverty

Poverty means going short materially, socially and emotionally. It means spending less on food, on heating and on clothing than someone on an average income—above all, poverty takes away the tools to build the blocks for the future. It steals away the opportunity to have a life unmarked by sickness, a decent education, a secure home. (p. 3)

Relative poverty introduces the idea that it is not enough simply to be able to meet the material necessities of life. One is poor if one lacks the resources required to engage in some meaningful ways in society and its sundry activities (social, economic, political, cultural, and recreational). That is, relative poverty is concerned with *living standards*—which vary by place and over time, but which convey the notion of comparatively full social functioning. This concept of relative poverty as the inability to function socially to

some normative standard can be traced in Western thought as far back as Aristotle (Sen 2000). Peter Townsend was one of the first of the recent theorists to criticize the policy use of absolute poverty:

He, and others since, argued for a concept of 'relative poverty' based less on minimal needs for survival and more on needs conditioned by societal expectations—that is, on what people require to participate fully in society (Nunes 2008; Eurostat 2010). This concept of relative poverty is actually reasonably old even in liberal economic thought, having been famously proposed by Adam Smith in his statement that 'a creditable day-labourer would be ashamed to appear in public without a linen shirt, the want of which would be supposed to denote that disgraceful degree of poverty' (cited in Ravallion 2011). (Labonté et al. 2012, p. 15)

As Martin Ravallion, the World Bank's expert on global poverty and lead analyst for the absolute measures discussed earlier, points out, this passage from Smith implies that 'certain socially-specific expenditures are essential for social inclusion, on top of basic needs for nutrition and physical survival' and that 'the way this idea is implemented in practice is to set a 'relative poverty line' that is a constant proportion of average income for the country' (Ravallion 2011). The common relative poverty measure is having a net household income (one that takes into account government cash transfers and taxes, and that is adjusted for family size and often also for urban or rural location) that is below 50 per cent of the country median. This measure is commonly used for comparative studies within or across high-income countries, i.e. those belonging to the Organization for Economic Cooperation and Development (OECD). Fig. 2.2.2 provides an example using

Fig. 2.2.2 Poverty rate and poverty gap, selected OECD countries.

Adapted with permission from Organisation for Economic Co-operation and Development (OECD), *OECD Factbook 2010: Economic, Environmental and Social Statistics*, OECD Publishing, p.237, Copyright © 2010, DOI: 10.1787/factbook-2010-en.

OECD countries, which includes the ‘poverty gap’—the median of how far below the relative poverty line a household falls and a measure of ‘deep poverty’ (OECD 2010). Fig. 2.2.3 focuses on child poverty in economically advanced countries (UNICEF Innocenti Research Centre 2012). A relative concept of poverty informs public health by expanding the range of goods and services that members of a household should be able to access to experience, in Ravallion’s terms, social inclusion, and the mental and physical health benefits such inclusion might garner. At the same time, the monetization of the concept (pegging it to a percentage of average or median income) has been criticized since it represents a form of poverty that will never disappear. As average or median incomes rise in a population, there will always be some who will fall below these cut-offs. It is possible for absolute poverty to fall within a country or region, while relative poverty rises; since the relative

poverty cut-offs can be affected by disproportionate increases in income amongst a minority of the population, even if the material conditions of those at the bottom of the income gradient improve. As the UNICEF Innocenti Research Centre (2012) warns, relative poverty is not a good metric for comparison across countries except for those wealthier nations where falling below 50 per cent of the median income does risk social exclusion (a concept we define later in this chapter).

Poverty as lack of capabilities

The capability approach...builds a bridge between absolute and relative concepts of poverty. It is absolute in identifying the capabilities or functionings that people should experience, but relative in the income or resources that may be required.

Reproduced from Labonté, R. et al., *Indicators of Social Exclusion and Inclusion: A Critical and Comparative Analysis of the Literature*, E/Exchange Working Paper Series, PHIRN, University of Ottawa, Canada © 2012, with permission from the author.

While relative poverty presents a more nuanced understanding of ‘being poor’ than does absolute poverty, it still relies upon indicators of income. Amartya Sen (1985), in his pioneering capability approach to poverty, focused attention on the infrastructural enabling conditions (‘capabilities’) that allow people to attain desirable states (‘functionings’), without which a minimally dignified human existence is not possible. This has brought in different kinds of indicators that are much more transparent and direct reflections of people’s actually achieved levels of well-being and ability ‘to accomplish what [they] value’ (Alkire 2002, p. 6, cited in Nunes 2008). Income is simply a means to a valued and socially purposeful end. Sen considered indicators such as life expectancy, literacy, and infant mortality to be important proxies for capabilities (at least at a population level) and more useful than income alone to identify poor from non-poor groups or countries. He proposed that indicators of these other characteristics should be aggregated into a more complex poverty measure (Nunes 2008). This approach became the basis of the *Human Development Index* (HDI), first released in 1990 and issued annually by the United Nations Development Program (UNDP), and which combines data on health, education, and living standards (this last dimension using the income indicator of log gross domestic product (GDP)/capita) (see Table 2.2.2) (UNDP 2011). The capability approach from which the HDI arose has since been considerably elaborated (Ranis et al. 2007), including the UNDP’s creation of a *multidimensional poverty index* (MPI) in which additional weighted measures have been added to its HDI (Box 2.2.1).

The key contribution the capability approach makes to public health is that it de-couples meaningful social participation (the concern of relative poverty) and, in broader conceptual terms, the notion of ‘development’ itself, from a purely or primarily economic growth/income growth model. It identifies a range of goods and services for which social (state) provision is important due to their cost or to market failures in ensuring equitable access. The capability approach arose, in part, to challenge the dominance in public policy of the GDP measure, which critics argued was a deeply flawed indicator of how well countries were doing in providing for the general health or welfare of their citizens.

While Sen (1999) argued effectively for the obligations on states to provide a minimum basket of resources allowing people to

HDI rank	Country	HDI value	
		1980	2011
	South Asia	0.356	0.548
	Sub-Saharan Africa	0.365	0.463
	World	0.558	0.682

Note: the top five countries in each of the first three categories (very high, high and medium) are shown, while for contrast purposes the bottom five countries for the fourth category (low) is shown.

Adapted with permission from United Nations Development Programme (UNDP), *Human Development Report 2011: Sustainability and Equity: A Better Future for All*, Copyright © 2011 by the United Nations Development Programme, available from http://hdr.undp.org/en/media/HDR_2011_EN_Complete.pdf.

develop their capabilities (hence their choice of ‘functionings’, including choices concerning their health), his collaborator in developing this theory, Martha Nussbaum, attempted to identify the contents of that basket:

1. Life: being able to live to the end of a human life of normal length; not dying prematurely, or before one’s life is so reduced as to be not worth living.

Box 2.2.1 Multidimensional poverty index

1. *Education* (each indicator is weighted equally at 1/6):

- ◆ Years of schooling: no household member has completed 5 years of schooling.
- ◆ School attendance: no school attendance in years 1–8.

2. *Health* (each indicator is weighted equally at 1/6):

- ◆ Child mortality: if any child has died in the family.
- ◆ Nutrition: if any adult or child for whom there is nutritional information is malnourished.

3. *Standard of living* (each indicator is weighted equally at 1/18):

- ◆ Electricity: the household has no electricity.
- ◆ Drinking water: the household lacks access to clean drinking water within a 30-minute walk from home.
- ◆ Sanitation: the household has no adequate sanitation or only a shared toilet.
- ◆ Flooring: the household has a dirt, sand, or dung floor.
- ◆ Cooking fuel: the household cooks with wood, charcoal, or dung.
- ◆ Assets: the household does not own more than one of: radio, TV, telephone, bike, motorbike, or refrigerator and does not own a car or tractor.

Reproduced with permission from Alkire, S. and Santos, M.E., *Measuring acute poverty in the developing world: Robustness and scope of the Multidimensional Poverty Index*, OPHI Working Paper 59, Oxford, UK, Oxford Poverty and Human Development Initiative, Copyright © 2013, also available from <http://www.ophi.org.uk/measuring-acute-poverty-in-the-developing-world-robustness-and-scope-of-the-multidimensional-poverty-index-2/>

2. Bodily health: being able to have good health, including reproductive health, to be adequately nourished; to have adequate shelter.
3. Bodily integrity: being able to move freely from place to place; being able to be secure against assault, including sexual assault, having opportunities for sexual satisfaction and for choice in matters of reproduction.
4. Senses, imagination, and thought: being able to use the senses, to imagine, think, and reason—and to do these things in a way informed and cultivated by an adequate education, including but not limited to literacy and basic mathematical and scientific training. Being able to use one's mind in ways protected by guarantees of freedom of expression with respect to both political and artistic speech. Being able to search for ultimate meaning of life in one's own way.
5. Emotion: being able to have attachments to things and people outside ourselves.
6. Practical reason: being able to form a conception of the good and to engage in critical reflection about planning one's life; Nussbaum recognizes that this entails protection for the liberty of conscience and religious observance.
7. Affiliation: being able to live with and toward others; to engage in various forms of social interaction; having the social bases of self-respect and non-humiliation; being able to be treated as a dignified being including protection against discrimination on the basis of race, sex, sexual orientation, religion, caste, ethnicity, or national origin.
8. Other species: being able to live with concern for and in relationship to the world of nature.
9. Play: being able to laugh, or play, to enjoy recreational activities.
10. Control over one's environment both politically and materially, including having the right to political participation and having property rights on an equal basis with others, having the right to seek employment on an equal basis with others (Nussbaum 2000, pp. 77–80).

Defining poverty as capability-failure, especially given the long list of positively stated attributes of 'flourishing' that Nussbaum provides, nonetheless risks taking policy attention away from income poverty. In commodified, wage-based market systems, income (and its quantity) represents both choice (capabilities) and power (Lister 2004). Money may not be everything, but adequate income (however adequacy is determined) remains basic to any understanding of poverty. We note that in some low-income countries market systems are less entrenched and access to the capabilities through subsistence farming and strong cohesive communities remain important protections against absolute poverty.

Poverty as deprivation

Deprivation...exists when people lack or are denied resources to participate in social and economic activities in the society in which they live.

Reproduced from Labonté, R. et al., *Indicators of Social Exclusion and Inclusion: A Critical and Comparative Analysis of the Literature*, E/Exchange Working Paper Series, PHIRN, University of Ottawa, Canada © 2012, with permission from the author.

Deprivation entered the poverty literature in the late 1960s (Yitzhaki 1979). Like poverty, deprivation has both absolute and

relative conceptualizations. As an absolute condition, deprivation is an undesired state that arises when people are unable to access necessary goods and services due to a lack of resources (Hallerod 1996); much depends here on where one draws a line under 'necessary' which immediately takes us into the terrain of relative deprivation. As a relative condition, deprivation exists when people lack or are denied resources to participate in social and economic activities in the society in which they live (Bailey 2004). One example is the UNICEF Innocenti Research Centre's measure of 'child deprivation' based upon the percentage of children aged 1–16 lacking two or more items from a list of 14 considered essential to acceptable child functionings in economically advanced countries (Fig. 2.2.4) (UNICEF Innocenti Research Centre 2012). Like relative poverty, the emphasis of relative deprivation is on *social participation*. The notion of being 'denied' resources for such participation is captured evocatively in deprivation as an 'enforced lack of socially perceived essentials' (Saunders et al. 2008, p. 175). Deprivation, like multidimensional poverty, can be multiple, when people lack access to sufficient levels of several attributes important to social participation, such as income, housing, healthcare, and education. Moreover, deprivation is an *enforced* state; that is, its origins can be traced directly to certain political, economic, or policy choices made by governments and which are entrenched in economic systems such as capitalism.

While emerging from the poverty literature, there are important conceptual differences between deprivation and poverty. A person may be poor in terms of income but not deprived in terms of, for example, housing, healthcare, education, or transportation, to the extent these are publicly subsidized or provided. Conversely, a person could experience deprivation in multiple dimensions while

Fig. 2.2.4 Child deprivation in selected countries. Data for 2009.

not being income poor, such as experiencing discrimination by virtue of one's gender, ethnicity, or sexual orientation (Saunders et al. 2008). This 'intersectionality' of social identity and health risk has become increasingly invoked as a way of incorporating a broader understanding of poverty and inequality, by exploring 'simultaneous intersections between aspects of social difference and identity (e.g. as related to meanings of race/ethnicity, indigeneity, gender, class, sexuality, geography, age, disability/ability, migration status, religion) and forms of systemic oppression (e.g. racism, classism, sexism, ableism, homophobia)' (Springer et al. 2012, p. 1661). It shifts an understanding of poverty well away from matters of simple material goods and physical functioning, which some critics argue deflects attention away from the financial needs of the many who live in absolute or relative poverty (Nolan and Whelan 1996), to a much broader concern with multiple forms of what has been termed *social exclusion*.

Poverty as social exclusion

Poverty and social exclusion refer to when people are prevented from participating fully in economic, social and civil life and/or when their access to income and other resources (personal, family, social and cultural) is so inadequate as to exclude them from enjoying a standard of living and quality of life that is regarded as acceptable by the society in which they live. In such situations people often are unable to fully access their fundamental rights. (p. 11)

Social exclusion extends beyond poverty and deprivation concepts by incorporating a broader understanding of social processes and their consequences (Bailey et al. 2004). Both poverty and deprivation are components of social exclusion but, as Berger-Schmitt and Noll (Berger-Schmitt and Noll 2000) point out, income-poverty can be both a cause and a consequence of social exclusion. But income-poverty is only one possible cause or consequence. As with deprivation, one can be wealthy (not poor) and still experience social exclusion, as has been the case with gay and lesbian people in many of the world's countries (Estivill 2003). Social exclusion, although sharing much in common with Townsend's concept of relative deprivation, differs in the emphasis it places on non-material aspects, from 'prospects and networks' (which work to reduce exclusion) to prejudice and discrimination (which work to increase it) (Saunders and Wong 2009).

Social exclusion first arose in research and policy discourse in France in the early 1970s, and was used both to explain the effects of extreme economic restructuring on social solidarity beyond what poverty and deprivation alone could describe, and to assist in developing policies to promote social cohesion within the European Union (Gore and Figueiredo 1997; Aasland and Flotten 2001; Rawal 2008). Rene Lenoir in 1974 was the first to coin the term as a way to define the condition of a large portion of the population that included the poor, handicapped, vulnerable, aged, abused children, substance abusers and other marginalized groups or 'social misfits' (de Haan 1999; Sen 2000). A broader conceptualization was later proposed to incorporate the 'social, economic, political and cultural systems which determine the integration of a person in society' (Walker 1997, cited in Lessof and Jowell 2000, p. 5)—that is, the social processes of exclusion.

Economic exclusion is a term frequently used synonymously with social exclusion. Dertwinkel (Dertwinkel 2008, p. 4) argues that the 'meaning of social exclusion has always been an economic and less a political or cultural one' and defines economic exclusion as a state of 'non-participation in or blocked access to the labor

market, public services, finance, housing, educational and health sector, among other possibilities'. (Labonté et al. 2012, pp. 19–20)

This emphasis on labour market attachment is most often encountered in European writing on social exclusion, even when other dimensions of exclusion are considered. Part of the reasoning behind this emphasis is that it creates greater social cohesion and reduces social conflict, given evidence that high levels of youth unemployment and poverty are associated in many countries with gang participation or rebel group involvement, motivated primarily by a desire to earn income (World Bank 2011). Other theorists, however, give greater attention to the *relational* aspects of social exclusion, linking exclusion to inadequate social participation, lack of social integration and lack of power (Room 1995, p. 5). As Sen (2000, p. 6) puts it, social exclusion (unlike poverty or deprivation) gives 'a central role to relational connections'. Work, like the income it generates, is simply one of the means of making such connections. This emphasis was echoed in the final report of the Social Exclusion Knowledge Network of the WHO Commission on Social Determinants of Health which distinguished between 'social exclusion as a state experienced by particular groups (common in policy discourse) as opposed to the relational approach... [in which] exclusion is viewed as a dynamic, multi-dimensional process driven by unequal power relations' (Popay et al. 2008, p. 7). This process results in unequal resources, reduced capabilities, and fewer claims on human rights leading to inequalities in access to entitled services. This perspective on social exclusion also points the policy spotlight at unfair economic and social structures rather than on deficiencies of individuals.

Gough et al. (2006) discuss social exclusion in terms of the ways in which it is an inevitability of neo-liberal capitalism. They acknowledge that it is a highly ambiguous concept (Gough et al. 2006, p. 49), and one that can be used to support a neo-liberal status quo by regarding as unproblematic the 'inclusion' of elite and wealthy groups whose privileges and practices contribute to the exclusion of others. They maintain that a broad notion of social exclusion should be centrally concerned with social oppression in particularly those of 'race', gender, sexuality, disability, and age. Crucially for the discussion in this chapter they note that the discourse of inclusion avoids confronting the question of justice and that 'one can be included in any social arrangement in an unjust fashion' (Gough et al. 2006, p. 4). As Levitas noted:

The term social exclusion is intrinsically problematic. It represents the primary... division in society as one between an included majority and an excluded minority. ... The solution... is a... transition across the boundary to become an insider rather than an outsider in a society whose structural inequalities remain largely uninterrogated. (Levitas 2005, p. 7)

Poverty summarized

Taking account of these various attempts to define and understand poverty, the concept might usefully be summarized as an absolute and comparative lack of resources and capabilities, comprised principally of the following:

1. Adequate material resources (food, shelter, clothing, and other normatively defined social necessities).
2. Income to acquire such necessities (generated through employment or government subsidies and transfers).

3. Access to formal labour markets or post-retirement or child-rearing income support (to provide adequacy and security of income, as well as access to social relations).
4. Access to adequate and affordable housing (extending beyond basic shelter to incorporate aspects of overcrowding, disrepair, insecure tenancy), and to services basic to health (e.g. sanitation, water).
5. Access to educational and healthcare opportunities (to improve access to formal labour markets and reduce barriers to broader forms of social participation).
6. Socially conditioned and structured forms of discrimination (which reduce access to formal labour markets, educational and healthcare opportunities, and broader forms of social participation).
7. Power or voice to influence the policy choices of governments affecting all of the above conditions (which extends to lack of political freedoms or human rights) (Labonté et al. 2012, p. 15).

There are finally three cautions about poverty that need issuing. The first is that poverty mobility can be dynamic, with people moving in and out of income- or consumption-based poverty (whether absolute or relative) even within short time periods. The chronic poor are those who 'remain trapped in situations and relationships which produce deprivation and capability losses over long periods' (Policy Analysis Discussion Group 2012, p. 6). The second is that people living in poverty, however conceptualized or measured, may not view themselves as poor, deprived, or without capabilities. 'Subjective' poverty differs from its objective measure, and may reflect people's perception of their agency, their rejection of the stigmatizing label of being one of 'the poor', or an internalized resignation to the inevitability of their circumstances. The third is that, just as poverty is now regarded as multidimensional, people's identities and capabilities are multiple. A focus only on people's relative deprivation without appreciating their relative capabilities risks creating or reinforcing resignation to their circumstances, rather than mobilization to change them.

How does poverty affect health and ill health affect poverty?

Whatever is going round, people in lower social positions tend to get more of it, and to die earlier even after adjustment for the effects of specific individual or environmental hazards. (p. 1355)

Reproduced with permission from *Social Science & Medicine*, Volume 31, Issue 12, Evans R. and Stoddart G., Producing Health, Consuming Health Care, pp. 1347–63, Copyright © 1990.

On average, the lower the socioeconomic position, the lower one's health status. Socioeconomic status (SES) is usually measured by income, occupation, or education, but also includes stratification by social class, gender, and race/ethnicity—examples of the intersectionality of different deprivations discussed earlier. One of the key findings in recent years has been that differences between social position and health status follow a gradient, a step-wise pattern between where one sits in a SES hierarchy and most health outcomes. Although not all health conditions follow a socioeconomic gradient (a few diseases are more common in higher than in lower SES groups) the pattern is robust, observed in many countries, persists over time, and is evident for all age groups and

for both men and women. Recent research has also shown that health inequities accumulate over a lifetime and that disadvantage at each stage of the life course affects health (Lynch et al. 1997; Smith et al. 1997, 1998). Adverse social and economic conditions in the early years of life are increasingly being shown to have a lifelong impact on health (Lynch and Smith 2005; Hertzman and Boyce 2010; Power et al. 2012). Much of this textbook is concerned with the determinants of the gradient in health; here, we recount briefly the three major explanatory models for this gradient: natural or social selection, cultural/behavioural, and materialist or structural (Baum 2008).

Natural or social selection

The social selection argument suggests that healthier people become wealthier people, enjoying greater social mobility than their poorer fellows. There is some evidence that better health is associated with social mobility, especially at younger ages; but this accounts for only a small portion of health differences between social groups (Whitehead 1992; Power et al. 1996). The social selection and mobility argument comes with its inverse: people are poor because they are unhealthy. Again, there is some evidence for this, particularly in low-income countries. We have already noted the problem of medical poverty, where the absence of affordable healthcare pushes sick people into poverty. There is also evidence that people living in countries with high burdens of particular diseases (such as HIV/AIDS, tuberculosis, or malaria) and with poor social protection safety nets (such as income transfers or sickness and unemployment benefits) can suffer greater poverty due to their illness reducing their ability to earn income. Poor health also contributes to poverty through its debilitating effects of inadequate nutrition on individual development and later economic productivity (Horton and Ross 2003; Sanders et al. 2007; Baum 2008). Early insults to the growth and brain development of children, even with intensive interventions later in life, are partially irreversible. In many cases, the damage is done even before the child is born. Undernutrition among mothers is a major reason why babies are born with a low birth weight, a result of small maternal size at conception and low pregnancy weight gain or inadequate food and energy intake during pregnancy (Kramer 1987). Malnutrition among infant girls is therefore one of the main routes for the intergenerational transmission of poverty (Horton and Ross 2003).

That sick people become poor, in other words, reflects the same dynamics of social stratification and material circumstances that explain why poor people are more likely to become ill in the first place. This accounts for why some wealthy but highly unequal countries with limited social protection can have poorer population health outcomes than poorer but more equal countries with high levels of social programme spending (notably for primary healthcare, education, women's literacy, land reforms, and physical infrastructure) (Balabanova et al. 2011). Sen (1999, pp. 335–6) showed this very clearly when he compared the life expectancies in the early 1990s of US whites with US African Americans, and with Indians in Kerala and the Chinese. While African Americans are very many times richer in income terms than the people in China and Kerala (even after correcting for cost of living differences) they are less likely to live as long. Sen explains this by reference to 'the social arrangements and community relations such as medical coverage, public healthcare, elementary education, law

and order, and prevalence of violence'. In other words: there is nothing 'natural' about 'social selection'; such selection arises as an effect of how the political and economic systems of countries are structured.

Cultural/behavioural explanations

A more commonly encountered reason for the SES gradient in health is that poorer people make unhealthier lifestyle choices. This is not a new argument. During the early decades of the nineteenth century Industrial Revolution in Europe, with its dislocating impacts on rural agricultural livelihoods and explosion of ghettos in rapidly expanding cities (a phenomenon now characteristic of many developing countries in late twentieth- and early twenty-first-century globalization) the poor were seen as a palpable disease threat to the rich. Their poverty, in turn, was not regarded as an effect of their economic dislocations, but as 'the interaction of the twin problems of indolence and vice' (Alcock 1993, p. 12). The British 'father' of public health, Sir Edwin Chadwick, in his reforms of the poor laws requiring urban paupers to earn their minimal allowance in workhouses, and so to become 'deserving poor', argued that:

The population so exposed is less susceptible to moral influences, and the effects of education are more transient than with a healthy population; these adverse circumstances tend to produce an adult population short-lived, improvident, reckless and intemperate, and with habitual avidity for sensual gratifications. (Chadwick 1930)

Even while acknowledging the 'adverse circumstances' of the poor, Chadwick posits that the poor health of the poor results primarily from their lack of the proper behaviours and morality of the healthier and wealthier. A more socially critical observer of the same era, Friedrich Engels, agreed with Chadwick that alcohol was fairly prevalent amongst the poor labouring classes, but that 'it was almost their only source of pleasure':

The working man comes home from his work tired, exhausted, finds his home comfortless, damp, dirty, repulsive; he has urgent need of recreation, he must have something to make... the prospect of the next day endurable. (Engels 1845/1999, p. 113)

The same dichotomy between a behavioural and a socially critical account of the poverty/health relationship persists today. Many (although not all) unhealthy behaviours do tend to be more prevalent as one moves down the social gradient. Even in developing countries undergoing nutritional transitions (where traditional diets are being replaced by increased consumption of high-fat, energy-dense, low-nutrient food commodities), what might begin as a status choice amongst a rising middle class quickly becomes a necessity choice (due to availability and cost) for poorer social classes (Drieskens et al. 2009; Monteiro et al. 2010; Stuckler and Nestle 2012). The same is true for smoking, originally more common amongst elite social classes, and, to lesser degrees, alcohol and other drug use (Drieskens et al. 2009). But explaining these behaviours as 'cultural' effects of poorer groups (their improvident or reckless 'lifestyle'), or as their lack of knowledge or motivation to adopt healthier patterns, ignores the social contexts that condition and constrain individual choice (Layte and Whelan 2009). It also fails to account for the excess disease burden faced by many poorer groups, even after accounting for all of the individual/behavioural risk factors (Lynch and Smith 2005).

Materialist or structural explanations

The limitation of a narrowly behavioural understanding of the poverty/health relationship draws attention to how the material conditions of poverty affect health. Here the enumeration of, and evidence for, the health determining effects of these conditions is plentiful, reflecting many of the material circumstances identified in this chapter's discussion of poverty and deprivation: access to income, housing, employment, nutritious food, safe water and sanitation, unemployment protection, health services, education services, and other socially provided resources that allow for the development of capabilities. These structural factors (so named because they reflect embedded economic and power relations within societies) are also related to what have been called psychosocial risk factors: the isolation, low social support, poor social networks, high self-blame, and low perceived power that are more frequent among poorer and less educated groups (Najman 1994; Lynch and Smith 2005; Kawachi et al. 2008). Racism has also been shown to have a powerful effect on health status (Krieger 2000; Paradies 2006; Ziersch et al. 2011), psychosocial and material risks cluster together, and poorer groups (those lower along the SES gradient) are more likely to experience all three. In countries where material inequalities have been significantly reduced through welfare measures, for example, health inequalities experienced by poorer groups are more likely to be a result of greater behavioural and psychosocial risks; although, as Johan Mackenbach, whose work is the topic of Chapter 2.3, suggests, 'the persistence of health inequalities in modern European welfare states can partly be seen as a failure of these states to implement more radical redistribution measures' (Mackenbach 2012, p. 761). Behavioural, psychosocial, and material risks matter and interact with each other (Krieger 2000; Paradies 2006; Ziersch et al. 2011).

What theories of justice should guide our interventions?

The public health concern with justice, poverty, and health enjoys a rich history. Over 150 years ago the young Prussian physician, Rudolf Virchow, hired by the government to recommend how to control a typhoid epidemic amongst poor coal miners, famously called for massive social reforms that ranged from progressive taxation and organized food cooperatives, to improved wages and working conditions, strong local government, improved education, and an end to church interference urging the poor to suffer now and to reap their rewards in heaven. Friedrich Engels, writing around the same time as Virchow, published his lengthy analysis of *The Condition of the Working Class in England*, leading to his co-authorship with Karl Marx of the influential *Communist Manifesto* with its call for a revolutionary social justice. Some of this early concern with poverty and its social and physical ills continued into the late nineteenth and into the twentieth century, although it became muted by the rise of 'scientific medicine' and its promise of a cure for most diseases. Supported by industrialist philanthropies (notably in the Americas, by The Rockefeller Foundation), scientific medicine's emphasis on cure rather than prevention deflected much public health attention away from the social roots of disease (Brown 1979; Tesh 1988). Poverty as a public health issue occasionally surfaced, especially during times of economic recession or depression when high poverty rates

were associated with the spread of diseases such as tuberculosis and cholera. But it was in Latin America that the radicalism of nineteenth-century public health activism became institutionalized in the practice of what has been called 'social medicine' (Waitzkin 2005). One of its major proponents was the Chilean physician (and later socialist President) Salvador Allende who, as health minister in the late 1930s and 1940s, approached health inequities in Chile as a direct result of historic underdevelopment, international economic dependency, and foreign debt. He argued that the 'medico-social problems of the country... require precisely the solution of the economic problems' (Waitzkin 2005, p. 740). Allende's reforms, echoing those of Virchow, included wage improvements, wealth redistribution, land reforms, improved food security measures, and publicly supported housing development.

More recently, the WHO Commission on the Social Determinants of Health (2008) took a clear stand that inequities in health (avoidable inequalities) were unacceptable and the goal of policy should be to eliminate these and so argued for closing the life expectancy gap in a generation.

These are bold public health proposals, generally framed in broadly stated concerns with justice (fairness). But how should we determine when poverty's health risks become unacceptable? What theories of social justice might guide our public health interventions or advocacy?

Equality of opportunity or equality of outcome?

Social justice theory is generally associated with European societies and particularly with struggles during the industrial revolution and the emergence of socialist, social democratic or other models of redistributive welfare states: 'Social justice is not possible without strong and coherent redistributive policies conceived and implemented by public agencies' (United Nations Division for Social Policy 2006, p. 6). Social justice theory is essentially concerned with equity, or fairness. On this basis, it is argued that social justice (equity) is a universal concern, since all social arrangements, to be legitimate and to function at all, must attend to issues of equality (Sen 1992). But there are subtleties to how equity is conceived with two main dimensions: equality of opportunity, achieved through procedural justice or 'horizontal equity' in which equals are treated the same; and equality of outcome, achieved through substantive justice or 'vertical equity' in which people are treated differently according to their initial endowments, resources, privileges or rights. Both equalities (opportunity, outcome) are ideal types; neither exists in 'true' form. They represent aspirational ideals of what societies strive to create for their members (fairness in outcomes) and how they believe this should be accomplished (fairness in opportunity). (Labonté 2010, p. 84)

There is a political, as well as philosophical, difference in these two broad social justice streams. (Labonté 2010, p. 84).

Recent decades of global market integration and the collapse of Soviet-style 'socialism' have been accompanied by the increasing dominance of neo-liberal ideology which has supplanted concerns with social justice by an exclusive focus on economic growth which, it is suggested, will eventually result in greater and better-distributed wealth—the trickle-down theory.

In turn, proponents of more open markets and conventional approaches to growth and development emphasize equality of opportunity, with only residual attention to equality of outcome. This was the position taken by the World Bank's 2006 *World Development*

Report on the theme of equity and development, which was less supportive of post-market income redistribution to achieve greater equality, instead favouring greater individual equality of opportunity through *inter alia* 'equality before the law, equal enforcement of personal and property rights, non-discriminatory institutions, and equal access to public services and infrastructure' (World Bank 2006, pp. 18–19). The slight nod to a concern with outcomes was reference to avoidance of absolute deprivation. (Labonté 2010, p. 84)

Theories of justice

Moral defense for some mitigation of health and social inequalities arising from poverty is a recurrent theme in much contemporary Western philosophy. Peter Singer (1972) posits 'a Greater Moral Evil Principle,' that it is both just and of collective benefit to act to relieve poverty and deprivation if, in doing so, we do not sacrifice something of comparable moral significance. Around the same time John Rawls published his highly influential *Theory of Justice*. Standing behind a 'veil of ignorance' as to their social standing at birth, Rawls argues that people would choose a justice that guaranteed a minimum of primary goods that any rational person would choose as basic to their needs. This justice theory builds upon two principles. The first principle is the 'priority of the equal' (basic liberties), which roughly equates with individuals having civil and political rights that protect them against excess authoritarian rule by the state. The second principle is based on legal equality of opportunity, which roughly equates with individuals having economic, cultural and social rights that obligate states to provide certain goods or services (the minimum resources or capabilities required to exercise one's functionalities). His second principle also invokes the 'difference principle': that inequality in the distribution of social and economic goods ('primary goods') are allowable only to the extent that they also improve the lot of the least advantaged. The difference principle obliges a degree of state interventions of redistribution and regulation, although Rawls did not believe that the extreme differences in wealth and power that markets create was of moral concern provided the conditions of the least advantaged improved. He also emphasized the centrality of better procedural justice (Schaefer 2007). (Labonté 2010, p. 85)

Rawls' justice theory is located within the social contract school, which views nation states as the primary actors in international relations. He held that poverty in low-income countries was primarily an effect of domestic policies and practices with little international or global causality. Pogge (2002), drawing on cosmopolitan arguments, challenges Rawls on this conclusion, as well as on evidence that poverty cannot be de-linked from global economic institutions and actors. In doing so, he extends Rawls' basic justice theory to a global level, contending that there are not simply 'positive duties' to assist those in need, but moral obligations (negative duties) to prevent harm (Pogge 2004).

Pogge's theory of relational justice (Pogge 2002) is based on three lines of argument:

1. The radical inequalities observed between peoples and nations today are partly an effect of a violent history in which some gained at the expense of others. While we individually cannot be held responsible for the actions of our forebears in this 'conquest,' as moral persons we can be held accountable for rectifying the vast disparities in initial conditions that this history has created.

2. Not only does procedural justice by itself fail to account for these vast disparities in initial conditions; it is impossible to conceive of these disparities existing on the scale that they do without 'an organized state of civilization' (Pogge 2005) to uphold them. Both procedural and substantive injustices thus endure.

3. There is evidence that economic institutions operating on an international scale (the ‘organized state of civilization’) have been complicit in upholding these injustices. There are also feasible alternatives to these economic institutions that would reduce the “radical inequality” of persisting poverty. Persons involved in upholding these institutions are thus implicated in creating subsequent ill health, even though they may be half-way around the world (Pogge 2004).

Pogge concludes that: ‘we are *harming* the global poor if and insofar as we collaborate in imposing an *unjust* global institutional order on them;’ and proceeds to offer an evidence-informed argument to establish that present global institutional rules and procedures are unjust (Pogge 2005, emphasis in original). The justice implication is one of immediately engaging in ‘rectification’ through strengthened human rights and more progressive systems of global resource redistribution; but also an obligation to change the very rules of economic governance in order to overcome the historic and radical inequalities in initial conditions. (Labonté 2010, pp. 85–6)

A similar theory of social justice has been argued by Iris Marion Young. Accepting that there are demonstrable ‘structural injustices’ that ‘put large categories of persons under a systematic threat of domination or deprivation of the means to develop and exercise their capacities, at the same time as these social processes enable others to dominate’ (Young 2006, p. 114), Young argues that ‘all agents who contribute by their actions to the structural processes that produce injustice have responsibilities to work to remedy these injustices’ (Young 2006, pp. 102–3). Her ‘social connection model’ of responsibility extends these moral obligations beyond those more directly (causally) liable to a larger body of people who may be only indirectly connected. An example she offers is responsibility for retaining developing country ‘sweatshops’, which includes those who shop at retailers sourcing their goods from such shops as well as the retailers and factory owners themselves. The limitation of this model is that its extensive diffusion of responsibility may limit the ability to enforce changes in practice.

The role of human rights

Several justice theories make reference to human rights. Not only do human rights conventions, ratified by most of the world’s states, represent a consensus on citizen rights and state obligations (Mack 2009), but there is widespread agreement that ‘poverty is the principal cause of human rights violations in the world’ (Office of the High Commissioner for Human Rights 1999, para. 9) and that ‘poverty constitutes a denial of human rights’ (Office of the High Commissioner for Human Rights 1999, para. 1). First established after the Second World War with the UN Declaration on Human Rights, several subsequent conventions have been agreed upon that detail specific citizen rights and state duties. These include the Covenant on Civil and Political Rights (intended to protect individuals against abuses of state authority) and the Covenant on Economic, Social and Cultural Rights (intended to guarantee individuals certain entitlements from the state); as well as specific treaties on the rights of children and women, racial minorities, indigenous peoples and numerous other facets of social justice. Together these treaties comprise an ‘International Human Rights Framework’ which, although lacking enforcement measures, empowers different UN committees and ‘special rapporteurs’ to review countries’ compliance with their legally binding

obligations. Central to concerns with the poverty/health relationship is Article 12 of Covenant on Economic, Social and Cultural Rights (technically known as the Right to the Highest Attainable Standard of Physical and Mental Health, see Chapter 3.3) and its General Comment 14, which identifies a broad range of actions required for the progressive realization of this right. Health is considered a basic right, since it is foundational to the enjoyment of most other human rights.

The right to health, when adopted in countries’ own constitutions or laws, however, can be and has been interpreted in legal decisions or national policy as an individual right only. Individual rights to treatment have been used to force public payment of costly medicines with opportunity costs to other facets of public health access of greater importance to the poor (Hogerzeil et al. 2006; Gianella-Malcam et al. 2009; Yamin and Parra-Vera 2009). International legal scholars argue that human rights emphasis, instead, should be placed on poorer and more vulnerable populations. This requires greater attention to collective rights. Collective rights are implied in General Comment 14 on the right to health (Committee on Economic Social and Cultural Rights 2000), and are explicit in the Declaration on the Right to Development (Office of the High Commissioner for Human Rights 1986). Though the right to development is not a binding treaty, it is considered to have some standing in international human rights law (Aguirre 2008) and has strong normative support through UN agencies especially in the context of the Millennium Development Goals.

Some activist scholars and civil society organizations argue against the present international emphasis on human rights for their lack of class and political economy analysis. Others contend that human rights, with their individualistic and legalistic focus, ‘are not sufficient to serve as ethical criteria in solving the fundamental problems of the absolute poor’ partly because within these static statements, the ‘poor are not invited... to articulate their moral needs and rights for themselves’ (Mack 2009, p. 11). At the same time, human rights are considered the most globalized social justice statements of our era; and human rights treaties are being used to advance policies to improve health and to assist the poor (Dasgupta 1995; Schrecker et al. 2010).

Inequalities in initial conditions

Confronting inequalities in initial conditions (the lives people are born into) is vital especially given the evidence cited earlier on the lifetime impact of adverse living circumstances in early life. A focus on initial conditions begins to blur the earlier distinctions between equality of opportunity (procedural justice) and equality of outcome (substantive justice). Equality of opportunity, to be just, requires vertical equity: a disproportionate provision of public goods and capability resources for those whom history’s conquests, and today’s political institutions, place in highly unequal initial conditions. Departing from the redistributive minimalism of the World Bank’s 2006 World Development Report, a later report of the Bank’s Latin American Development Forum argues that:

A better understanding of the importance of inequality of opportunity in the determination of inequality of outcomes may change attitudes towards redistribution. People dislike and consider unfair inequalities associated with differences in circumstances, which many argue should be compensated for by society. By highlighting that component of inequality attributable to circumstances,

this type of analysis can help build a social and political consensus on... the best means for addressing inequality of opportunity. (p. 50)

Reproduced with permission from Ricardo Paes de Barros et al., *Measuring inequality of opportunities in Latin America and the Caribbean*, World Bank Publications, Washington, USA, Copyright © 2009 The International Bank for Reconstruction and Development/The World Bank.

What remains at issue is the extent of moral (or legal) obligation for amelioration of gross inequalities in initial conditions that create 'shortfall inequalities in central health capabilities' (Ruger 2008, p. 440). Is there an ethically defensible scale of rectification?

There is no answer to this question, apart from the imperative to seek one. In this quest, norms of procedural justice re-assume importance. Boggio (2009), in an argument for why international organizations and those within them have an ethical obligation to act to redress systematic health inequalities arising from poverty, addresses *how* such policy decisions can be made in a just manner. He identifies three basic principles for an 'ethically-informed deliberative process': publicity (transparency in process, a comprehensible rationale, and public argument and evidence); relevance (trust in actors/institutions by recipients, opportunity for wide participation, and interventions based on recipients' needs, values and aspirations); and revisability (policies and programmes can be challenged over time and improved, and individuals and institutions can be held accountable to purpose) (Boggio 2009). Several of these conditions are similar to principles of good governance widely held by governments and multilateral organizations; that is, they can be considered as having a broad normative base.

What public policies will reduce poverty?

The last decade of research on the causes of chronic poverty has shown that a *key factor in keeping certain categories or social groups in a state of chronic poverty* (transmitted through the generations) is the operation of power relations which stigmatise the people involved, undermine their confidence, and systematically close off options for individual or collective advancement... A stronger focus on structural inequalities, on systematic obstacles to redistributive processes and on social groups and interactions between them is part of this. (p. 6, emphasis in original)

The first issue public health confronts in grappling with the poverty, health, and justice relationship is simply this: if it is possible to improve the health of the poor without necessarily reducing income inequalities or relative poverty, is this sufficient? Some of the justice theories cited earlier might be content with saying yes to this, as their emphasis was more on absolute than on relative poverty. More recent poverty theories (capabilities, social exclusion/inclusion), however, give greater emphasis to the core value of ensuring human dignity or 'flourishing'. There is no justice if one simply survives; one must be able to live with purpose and meaning. Public health concern with poverty, then, extends beyond simply the specific disease risks poverty creates (both for the poor, and for the non-poor), to the existence of poverty itself—both absolute and relative.

The existence of poverty is inherently political, and there are different political theories for how poverty might be reduced. Alcock

(1993) distils these to four dominant models: neo-liberalism, conservatism, social democratic, and socialist, to which Gough et al. (2006) add a fifth: the associational.

The *neo-liberal model* is associated with policy responses to the declining profit rates, economic recessions, and developing world debt problems that arose in the 1970s and 1980s. Promoted by conservative governments in the United Kingdom, United States, and Germany (in the 1970s, the major economic powers in the world), neo-liberalism is based on a belief that free markets, sovereign individuals, free trade, strong property rights, and minimal government interference is the best means to enhance human well-being. Its policy platform rested on what became known in later years as the 'Washington Consensus': privatization, deregulation, tax reform (lower corporate and marginal rates), deficit reduction, and trade and financial liberalization. In general, the neo-liberal view is that governments should avoid poverty reduction as a policy matter, and instead rely upon economic growth through stronger free markets and economic liberalization to 'trickle down' and lift the poor out of their condition. Extreme neo-liberals have argued that the state should not interfere at all with conditions of poverty (Murray 1984), although this was rarely pursued as a policy option. Instead, neo-liberal-dominated governments tend towards a 'welfare minimalism', with benefits or entitlements at a level that prevents the worst forms of deprivation, but that is rarely sufficient for 'flourishing' or 'health capabilities'.

The *conservative model* overlaps with the neo-liberal, although it holds to the importance of some state intervention to ameliorate the worst inequities arising from markets, and specifically market failures (Alcock 1993). Persisting chronic poverty is symptomatic of market failures, implying that free markets and economic growth are unable, by themselves, to create equal opportunities for all. Conservative policies are not aimed at preventing poverty, which would require strong regulation of markets, but with relieving the worst of its effects. The approach is selective (means-tested benefits), often punitive (distinguishing between the 'deserving' and the 'undeserving' poor, the latter being people who could work even if their employment kept them in relative poverty), and minimalist (offering supports well below the minimum wage that could be earned in work, thus creating an incentive to 'labour market attachment').

The *social democratic model*, historically associated most with northern European countries, but also found in other parts of the world, emphasizes universalism in its poverty reduction policies. Social democracies are often highly interventionist in markets to prevent poverty in the first instance, as well as using high taxation and social spending to reduce residual levels of poverty. As with the previous two models, there is still an emphasis on labour market participation and an expectation that those who can engage in work will do so. But there is also greater emphasis on extending positive incentives to people entering lower-waged positions to overcome what has been called the 'welfare wall', a term that describes the loss of non-income benefits when moving off social assistance to minimum waged positions. Although universalism in benefits and entitlements helps to build cross-class solidarity, the non-income benefits of social spending (e.g. in healthcare, education, transportation services, and the like) can be disproportionately 'captured' by wealthier social groups. This has led to calls for 'proportional universalism' in which policies are constructed such that those in greater need enjoy disproportionate levels of

benefits (Marmot 2010); and for some degree of targeting of benefits to maximize their poverty reducing efficiencies (OECD 2008).

The *associational model* also reflects opposition to neo-liberalism and is based on the need to involve people in economic models and reduce the extent to which they are alienated by them (Gough et al. 2006). Building strong social capital, voluntary organizations, and civil society are considered to be the key poverty-reducing components. Micro credit banks such as the Grameen Bank are an example in low-income countries where (mainly) women can obtain loans to set up their own business. A further example is the Indian Self-Employed Women's Association, which organizes millions of women to provide their own banks, workers' cooperatives, child care, and health and unemployment insurance. In rich countries, examples would be locally based bartering systems, food and worker cooperatives. These initiatives are based on self-help, are democratically run, have a local focus, and depend on forms of collectivity that can be plural, multiple, and diverse. Gough et al. (2006) indicate that the expectation is that states should be subordinate to these myriad local organizations and that political democracy should grow out of the practical economic and social democracy. They go on to note that associationalist projects are usually hemmed in by disciplinarian capital and the localist strategies leave the power structures that create poverty in the first place untouched.

The *socialist model*, though less prominent in recent decades since the collapse and failure of the Eastern Bloc countries, holds that capitalist market systems inevitably create poverty and that the only enduring means to reduce poverty is to replace capitalism with a socialist system of governance. This implied a radical transformation of capitalist labour markets, which inevitably create unemployment and poverty, to socialist (collective) forms of production and ownership. In the absence of a political revolution, the entrenchment of neo-liberal politics and ideology means that a process of transition to a socialist society needs to be envisaged. Moves towards greater egalitarianism include: protection of workers' conditions and rights; progressive taxation and tax enforcement measures for the wealthy and corporations; combating the multiple forms of discrimination in jobs, housing, and public services; withdrawal of public support for private education and health; public provision of good quality education and health services; provision of universal lifelong social security for all citizens; and maintaining public spaces for community use. Many of the critiques of market economics made by socialism are finding more policy and media traction in the wake of the 2007 global financial and employment crises; accompanied by civil society calls for progressive taxation, stronger market regulations, and enforceable citizen rights to hold government to account (Labonté and Schrecker 2009).

The role of policy initiatives and civil society mobilization for poverty reduction and fairer societies

Most countries have organized civil society groups, including labour organizations, campaigning for policy actions to reduce poverty. These groups generally blend the broad approaches of the social democratic and revolutionary socialist models. They often provide detailed policy analyses and briefs, and collaborate with some academic researchers to ensure the empirical and theoretical

integrity of their work. Some groups focus on reducing poverty while others argue that poverty reduction will only result from a broader reform of the economic system and the inequities to which it gives rise. There are several examples in history of social and labour movement mobilization forcing changes in government and social policies, including those directly related to poverty reduction and health improvement (Szreter 2003). We offer two here, one a governmental example and the other capturing civil society activism.

Brazil's governmental reforms

Significant gains in poverty reduction, health system development, and health outcomes have been achieved in several countries through progressive social policies, resulting ultimately from political mobilization. Brazil's progress over the past 20 years provides a contemporary example of progressive change within a market economy. Infant mortality, for example, fell from 114 per 1000 live births in 1970 to just 19.3 per 1000 live births in 2007, while life expectancy at birth increased by almost 40 per cent, reaching 72.8 years in 2008. It is not possible (or even likely) to attribute these impressive advances to health sector activities alone, since these activities were part of several large-scale social reforms initiated in the country. These reforms led to steep increases in school attendance and decreases in illiteracy rates, both of which are pathways to better health. As well, Brazil's gross domestic product doubled between 1981 and 2008, potentially lifting more families out of income poverty; and its high levels of income inequality fell substantially as a result of such social policies as the Bolsa Família conditional cash transfer programme, which covers 10.5 million families, and increases in the legal minimum wage. Other social determinants of health were also improved substantially, including increases in provision to households of indoor water, sewage disposal and electricity (Paim et al. 2011). Sustained and significant investment in the creation of a universal health system, the centrepiece of which is the Family Health Programme, is mostly directed at providing more accessible and equitable health services, particularly at the primary level, but also engages community health workers who identify in their localities social factors that negatively affect socioeconomic and health status and enrol other sectors in addressing them (Macinko et al. 2007; People's Health Movement et al. 2011).

The political context of Brazil's reforms dates back to the late 1980s when popular mobilization challenged a conservative government with strong pro-market policies. This mobilization against a military dictatorship brought together oppositional political parties (at the time, illegal), grassroots groups, progressive academics and researchers, and trade unions. This movement catalysed the institution of many progressive health policies. With the election of the Workers' Party in 1989, popular mobilization waned as progressive social policies were introduced, although 'social participation' in local government continues through such bodies as the National Health Council, which plays an ongoing role in democratizing policy development (Paim et al. 2011). In 2013, 'middle-class' protests began once again in Brazil, which some attribute to the country's targeting of many of its social reforms to the poorest sectors of the population. The challenge now is to universalize the benefits of these reforms, building the cross-class solidarity that remains important in sustaining support for redistributive social protection programmes (People's Health Movement et al. 2011).

Civil society challenges to unhealthy globalization

Another important recent example of civil society activism that catalysed far-reaching policy change that indirectly impacts on health equity is the campaign against the Multilateral Agreement on Investment (MAI). The Association for the Taxation of Financial Transaction for the Aid of Citizens (ATTAC) was founded in France in 1998 to mobilize support for the Tobin tax on currency transactions as part of a broader movement against inequitable globalization arising from cross-border speculative finance. ATTAC, which has now established itself in many countries, played a leading role in France's decision to withdraw from OECD talks on the MAI, resulting in the failure of the talks (Waters 2004).

The People's Health Movement (PHM), another global civil society group, is a grassroots organization linking health activists around the world. It was formed following the First People's Health Assembly in 2000 and its political position is outlined in the People's Charter for Health (People's Health Movement 2009) and summarized in the Preamble as:

Health is a social, economic and political issue and above all a fundamental human right. Inequality, poverty, exploitation, violence and injustice are at the root of ill-health and the deaths of poor and marginalised people. Health for all means that powerful interests have to be challenged, that globalisation has to be opposed, and that political and economic priorities have to be drastically changed.

Reproduced with permission from People's Health Movement, The People's Charter for Health, Copyright © 2009.

The Charter goes on to call for much broader political, economic, and social participation from poor people. Since 2000 the PHM has grown to encompass around 70 national circles which are organized into regional networks. A Right to Health campaign, whose parameters have been defined at a global level but whose country-level activities vary according to context and conjuncture, has placed the responsibility for poverty reduction and the reduction of health inequities firmly on the shoulders of national states and international organizations. PHM has also collaborated with other organizations to produce three editions of a publication, 'Global Health Watch' (<http://www.ghwatch.org>), which present alternative and more progressive versions of the World Health Reports produced by the World Health Organization. The GHWs provide a critical 'watch' on international organizations including the World Bank and the World Health Organization; offer evidence-informed critiques of neoliberal globalization; and argue strongly for its replacement by a more just and equitable system of global governance and economic system to achieve poverty eradication and health equity.

Conclusion

This chapter has analysed the various definitions of poverty and considered their philosophical and political implications. We have examined a variety of explanations for why poverty affects health adversely. On the basis of this examination we concluded that poverty reflects structural features of global and national economic and social systems and, in particular, that unequal societies give rise to greater poverty. We examined the norms of justice that can guide policy interventions to reduce poverty and its causes. We argued that both equality of opportunity and outcome are essential considerations in public policy and that confronting

inequalities in initial conditions is vital. Political responses to poverty reflect philosophical and ideological positions. Social democratic and socialist responses place emphasis on tackling the underlying structural causes of poverty and seek to provide non-stigmatizing supports to those living in poverty. Socialism also seeks to replace capitalist modes of production with those that socialize both production and profits and argues that a transition to such an economy would result in a significant reduction in poverty. Despite the efforts of many civil society groups around the world, poverty or near poverty, and its health consequences, although showing recent decline, are still the reality for about half of the world's population. This fact, together with growing economic inequities, does suggest that a new world economic and social order are required to dramatically reduce or eliminate poverty and the adverse health outcomes to which it gives rise.

Socioeconomic inequalities in health in high-income countries: the facts and the options

Johan P. Mackenbach

Introduction to socioeconomic inequalities in health in high-income countries

At the start of the twenty-first century, all high-income countries are faced with substantial inequalities in health within their populations. People with a lower level of education, a lower occupational class, or a lower level of income tend to die at a younger age, and to have, within their shorter lives, a higher prevalence of all kinds of health problems. This leads to large differences between socioeconomic groups in the number of years that people can expect to live in good health ('health expectancy').

Socioeconomic inequalities in health currently represent one of the greatest challenges for public health worldwide. This chapter aims to review the available evidence on the magnitude and explanation of these health inequalities (the 'facts'), and to present the available evidence on what we can do to reduce health inequalities (the 'options'). Socioeconomic inequalities in health will be defined as systematic differences in morbidity or mortality rates between people of higher and lower socioeconomic status, as indicated by, for example, level of education, occupational class, or income level.

This chapter only deals with the situation in high-income countries. Wherever possible, we will draw upon international overviews, such as comparative studies, in order to avoid biases related to the selective experiences of single countries. Most of the illustrations will be drawn upon the European experience, which has become very well documented in the past three decades.

Historical notes

Historical evidence suggests that socioeconomic inequalities in health are not a recent phenomenon. However, it was only during the nineteenth century that socioeconomic inequalities in health were 'discovered'. Before that time, health inequalities simply went unrecognized because of lack of information. In the nineteenth century, great figures in public health, such as Villermé in France, Chadwick in England, and Virchow in Germany, devoted a large part of their scientific work to this issue (Ackerknecht

1953; Coleman 1982; Chave 1984). This was facilitated by national population statistics, which permitted the calculation of mortality rates by occupation or by city district. Louis René Villermé (1782–1863), for example, analysed inequalities in mortality between 'arrondissements' in Paris in 1817–1821. He showed that districts with a lower socioeconomic level, as indicated by the proportion of houses for which no tax was levied over the rents, tended to have systematically higher mortality rates than more well-to-do neighbourhoods. He concluded that life and death are not primarily biological phenomena, but are closely linked to social circumstances (Coleman 1982). Rudolf Virchow (1821–1902) went even further in his famous statement that 'medicine is a social science, and politics nothing but medicine at a larger scale' (Mackenbach 2009).

Since the nineteenth century, there has been a marked decline in mortality in all current high-income countries, leading to a doubling of average life expectancy at birth. As a result, some inequalities in mortality have declined as well, but this is far from a generalized phenomenon. For example, in England and Wales, the only European country where long time-series about occupational class differences in mortality are available, inequalities in infant mortality declined substantially between the 1920s and 1970s, but over the same period inequalities in adult mortality remained largely stable in absolute terms, and even increased in relative terms (Pamuk 1985). Since then, further increases have been observed in many high-income countries (Mackenbach et al. 2003), and these have contributed to a heightened awareness of health inequalities, and of the challenge they pose to public health policy, around the world.

The start of the resurgence of an active interest in health inequalities in Europe can be linked to the publication of the Black Report in England in 1980 (Department of Health and Social Services 1980), which has been followed by an enormous rise of descriptive studies in many other countries, testifying to the existence of substantial inequalities in health in all countries with available data. Gradually the emphasis of academic research in this area has shifted from description to explanation, not only to

satisfy scientific curiosities but also to find entry-points for policies and interventions to reduce health inequalities (Mackenbach and Bakker 2002; Marmot and Wilkinson 2006). This was greatly facilitated by increased research funding, both from national research programmes (e.g. in England, the Netherlands, and Finland), and by international agencies (e.g. the European Commission and the European Science Foundation) (Siegrist and Marmot 2006).

As a result, our understanding of the causes of socioeconomic inequalities in health has expanded tremendously, and has allowed interested policymakers to start searching for strategies to reduce these inequalities. While countries are in different stages of policy development in this area (Whitehead 1998), the World Health Organization has actively promoted the issue of health inequalities by creating a Commission on Social Determinants of Health that has issued a major report urging policy action to ‘close the gap in a generation’ (Commission on Social Determinants of Health 2008). In some countries (e.g. England) political windows of opportunity have arisen which have led to national programmes to tackle health inequalities, the results of which are gradually becoming clear (Department of Health 2010), pointing to a need to double our efforts to find effective interventions and policies that can be implemented on a sufficiently large scale to achieve population-wide impacts (Mackenbach 2011).

The facts: description

Socioeconomic position should be measured by individual-level indicators like education (e.g. highest completed level of education), occupation (e.g. occupational class), or income (e.g. household income adjusted for household size), but can sometimes only be measured by area-level indicators (e.g. neighbourhood deprivation). Usually, all these indicators point in the same direction, with health being worse for those in lower socioeconomic positions, but there is often substantial variation between indicators in the strength of the association, suggesting that the underlying aetiological mechanisms are different as well (Galobardes et al. 2007).

The magnitude of socioeconomic inequalities in health can be measured in different ways, ranging from simple measures like rate ratios and rate differences (indicating relative and absolute differences in morbidity or mortality rates between two contrasting groups), to more complex measures like the relative index of inequality and the slope index of inequality (indicating relative and absolute differences in rates between those with the lowest and highest socioeconomic position, taking all groups into account and calibrating the social position of each group to its relative size) (Mackenbach and Kunst 1997). Although the choice of measure will partly depend on technical considerations, each emphasizes different aspects of health inequalities, often at the expense of others, and it may therefore be important to combine different measures (Harper et al. 2010).

Socioeconomic inequalities in health usually present themselves as a gradient, in the sense that there is a stepwise increase of rates of morbidity and mortality with every step down the social ladder, implying that social inequality affects the health of nearly everybody, not only the worst-off. This suggests that explanations should be sought in factors operating across society (Marmot 2003, 2004), and that policies to reduce health inequalities should do more than closing the gap between the worst- and best-off (Graham 2004).

Mortality

Total mortality

In all high-income countries with available data, mortality rates are higher among those in less advantaged socioeconomic positions (Mackenbach 2006; Commission on Social Determinants of Health 2008). Fig. 2.3.1 shows that the relative index of inequality is greater than 1 for both men and women in all countries, indicating that, throughout Europe, mortality is higher among those with less education (Mackenbach et al. 2008). Relative inequalities in mortality are seen at all ages, and are often largest in early middle age, but because of the higher average mortality rates at older ages, absolute inequalities tend to rise with age (Huisman et al. 2004).

The magnitude of these inequalities varies substantially among European countries. For example, in Sweden, the relative index of inequality for men is less than 2, indicating that mortality among those with the least education is less than twice that among those with the most education; on the other hand, in Hungary, the Czech Republic, and Poland, the relative index of inequality for men is 4 or higher, indicating that mortality differs by a factor of more than 4 between the lower and upper ends of the education scale. The smallest inequalities for both men and women are found in the Basque country of Spain, whereas the largest inequalities are found in the Czech Republic and Lithuania. Education-related inequalities in mortality are smaller than the European average in all southern European populations and larger than average in most countries in the eastern and Baltic regions. Similar patterns are seen for occupation-related inequalities in mortality among middle-aged men (Mackenbach et al. 2008).

Within Europe, the international pattern observed for relative inequalities in mortality also applies to absolute inequalities in mortality, as indicated by the slope index of inequality. This is because countries with larger relative inequalities in mortality, i.e. those in the eastern and Baltic regions, also tend to have higher average rates of mortality. As a result, the range of variation of absolute inequalities in mortality is even larger than that seen for relative inequalities. The magnitude of absolute inequalities in mortality varies more than sixfold among men and more than 20-fold among women, suggesting that there is an enormous scope for reducing inequalities in mortality (Mackenbach et al. 2008).

While the mortality rates of the higher educated are rather similar in different countries, the mortality rates of the lower educated are much more variable, and higher in countries with larger inequalities in mortality. In other words, the mortality rates among the lower educated drive the magnitude of inequalities in mortality in a country. It is as if the higher educated manage to keep their mortality levels low, regardless of national conditions, whereas the lower educated are more vulnerable to unfavourable national conditions (van Raalte et al. 2011).

Cause-specific mortality

Countries do not only differ in the magnitude of their inequalities in total mortality, but also in the causes of death contributing to higher mortality in lower socioeconomic groups (Table 2.3.1). Within Europe we observe three different ‘regimes’ of inequalities in cause-specific mortality: a North-western regime with large inequalities in mortality from cardiovascular disease (men and women) and cancer (men only); a Southern regime with small

Fig. 2.3.1 Relative inequalities in mortality by level of education in 16 European countries, 1990s. Note: the graph shows the relative index of inequality, indicating the rate ratio of mortality between those with the lowest and the highest socioeconomic position. This is a regression-based measure that takes into account all socioeconomic groups and calibrates the social position of each group to its proportion in the total population.

From the *New England Journal of Medicine*, Mackenbach, J.P. et al., Socioeconomic inequalities in health in 22 European countries, Volume 358, Issue 23, pp. 2468–81, Copyright ©2008 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.

inequalities in mortality from cardiovascular disease (men and women) and large inequalities in mortality from cancer (men only); and an Eastern regime with huge inequalities in mortality from cardiovascular disease, cancer and injuries (men and women) (Table 2.3.1) (Huisman et al. 2005a; Mackenbach et al. 2008).

Whereas mortality from stroke is always higher in the lower socioeconomic groups, this is not the case for ischaemic heart disease (IHD) (Avendano et al. 2004). For IHD, a North–South gradient within Europe has been found, with relative and absolute inequalities being larger in the North of Europe (e.g. the Nordic countries and the United Kingdom) than in the South (e.g. Portugal, Spain, and Italy) (Kunst et al. 1999; Mackenbach et al. 2000; Avendano et al. 2006).

This international pattern for IHD results from differences between countries in how the ‘epidemic’ of IHD has developed over time. In many countries, particularly in the North of Europe, mortality from IHD increased substantially after the Second World War, probably as a result of changes in health-related behaviours, such as smoking, diet, and physical exercise. During the 1970s, however, a decline set in, and is still continuing. During this epidemiological development, important changes occurred in the association between socioeconomic position and IHD mortality. In the North of Europe, during the 1950s and 1960s IHD mortality was higher in the higher socioeconomic groups, leading to the notion of IHD being a ‘manager’s disease’.

It was only during the 1970s, coinciding with the start of the decline of IHD mortality in the population as a whole, that a reversal occurred, and the current association emerged (Marmot and McDowall 1986; Gonzalez et al. 1998). This is due to differences between socioeconomic groups in both the timing and the speed of decline of IHD mortality. In the South of Europe, however, a similar ‘epidemic’ of IHD mortality has not occurred, and similar inequalities in IHD mortality have not arisen, partly as a result of the protection of traditional Mediterranean living habits against IHD (Avendano et al. 2006). These smaller inequalities in IHD explain much of the smaller inequalities in total mortality in Southern Europe, and suggest that the latter do not result from effective policies to reduce inequalities.

Inequalities in mortality from cancer are often large among men, partly because of the excess lung cancer mortality in lower socioeconomic groups (Menvielle et al. 2007; Menvielle et al. 2008; Van der Heyden et al. 2009). Among women, inequalities in cancer mortality are often smaller than among men. Sometimes they are really small or even have a ‘reverse’ direction, with higher mortality among the higher educated, particularly in Southern Europe (Mackenbach et al. 2008). This is because lung cancer mortality does not (yet) have the same negative association with socioeconomic status among women as it has among men, and because the most important cause of cancer mortality among women, breast cancer, often has a ‘reverse’ association with socioeconomic position (Strand et al. 2007). Both reflect the diffusion of ‘modern’ patterns of behaviour (i.e. smoking and delayed age of child-bearing) among women, with women in the North-western part of Europe and women in higher socioeconomic groups adopting these behaviours first (Cavelaars et al. 2000).

Unfortunately, the favourable situation in women, with small or absent socioeconomic inequalities in total cancer mortality, is likely to be a temporary phenomenon. In some countries in Western Europe, it has been found that in younger birth cohorts rates of breast cancer mortality now tend to be higher in lower socioeconomic groups than in higher socioeconomic groups. For lung cancer, there are similar indications for a future change in gradient among women (Mackenbach et al. 2004; Van der Heyden et al. 2009).

External causes of injury (road traffic accidents, other accidents, and suicides) are another important contributor to socioeconomic inequalities in mortality, particularly (but not exclusively) in Eastern Europe. Mortality from road traffic accidents, from suicides and from homicides is higher in lower socioeconomic groups among men, but not or less clearly so among women (Borrell et al. 2005; Lorant et al. 2005; Stickley et al. 2012). The larger inequalities in injury mortality in Eastern Europe are likely to be related to

Code numbers of the causes of death according to the 9th and 10th revisions of the *International Classification of Diseases, Clinical Modification* (ICD-9-CM and ICD-10-CM) are given in table 1 of the supplementary appendix in Mackenbach et al. (2008). The slope index of inequality is a regression-based measure of absolute differences in mortality rates between the lowest and the highest ends of the socioeconomic scale. NA denotes not available.

^a Age-standardized rates of death for all educational groups are given.

^b Rates of death from breast cancer among men are not given.

^c Alcohol-related causes are accidental poisoning by alcohol and alcoholic psychosis, dependence, abuse, cardiomyopathy, and cirrhosis of the liver and pancreas.

^d Smoking-related causes are chronic obstructive pulmonary disease and cancer of the buccal cavity, pharynx, oesophagus, larynx, trachea, bronchus, and lung.

^e Causes amenable to medical intervention are tuberculosis and other infectious and parasitic diseases, cervical cancer, breast cancer, Hodgkin's disease, leukaemia, hypertension, cerebrovascular disease, pneumonia or influenza, appendicitis, hernia, peptic ulcer, cholelithiasis and cholecystitis, and complications of childbirth.

Note: the slope index of inequality indicates the mortality rate difference between those with the lowest and the highest socioeconomic position. It is a regression-based measure that takes all socioeconomic groups into account and calibrates the social position of each group to its proportion in the total population.

From the *New England Journal of Medicine*, Mackenbach, J.P. et al., Socioeconomic inequalities in health in 22 European countries, Volume 358, Issue 23, pp. 2468–81, Copyright ©2008 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.

higher rates of excessive alcohol consumption (Mackenbach et al. 2008).

As is clear from Fig. 2.3.1, inequalities in mortality tend to be smaller among women than among men. This is partly because of a different cause-of-death pattern among women (with, e.g. high mortality rates from breast cancer, which as noted earlier happens to have 'reverse' inequalities), partly because of smaller inequalities among women (e.g. no clear socioeconomic gradients for road traffic and suicide mortality among women) (Mackenbach et al. 1999).

Trends

Mortality differences between socioeconomic groups have widened considerably in many European countries during the last three decades of the twentieth century. For relative inequalities this widening has been seen in all countries with available data; absolute inequalities, on the other hand, have remained stable in some countries and increased in others (Mackenbach et al. 2003; Wamala et al. 2006; Krieger et al. 2008; Strand et al. 2010; Shkolnikov et al. 2012).

The explanation of this disturbing phenomenon is only partly known. One aspect which should certainly be taken into account, however, is that this widening is generally the result of a difference between socioeconomic groups in the speed of mortality decline. While mortality declined in all socioeconomic groups, the decline has been faster in the higher socioeconomic groups than in the lower. The faster mortality declines in higher socioeconomic groups were in their turn mostly due to faster mortality declines for cardiovascular diseases (Mackenbach et al. 2003).

In many developed countries, the 1980s and 1990s have been decades with substantial improvements in cardiovascular disease mortality. These have been due to improvements in health-related behaviours (less smoking, modest improvements in diet, more physical exercise, etc.), and to the introduction of effective health-care interventions (hypertension detection and treatment, surgical interventions, thrombolytic therapy, etc.) (Unal et al. 2005). While these improvements have to some extent been taken up by all socioeconomic groups, the higher socioeconomic groups have tended to benefit more.

The widening of the gap in death rates has been particularly strong in Eastern Europe, probably as a result of economic and social developments following the political changes around 1990 (Leinsalu et al. 2009). Since these transitions, mortality rates have changed dramatically in many countries in Eastern Europe, with increases followed by declines in many countries. The temporary increases in mortality were due to a combination of (interlinked) factors: a rise in economic insecurity and poverty; a breakdown of protective social, public health, and healthcare institutions; and a rise in excessive drinking and other risk factors for premature mortality (McKee 2009).

The evidence clearly shows that these changes in mortality have not been equally shared between socioeconomic groups: in the countries with available data, mortality rates have generally increased more, or declined less, in the lower socioeconomic groups. Apparently, people with higher levels of education have been able to protect themselves better against increased health risks, and/or have been able to benefit more from new opportunities for health gains. Evidence from several Eastern European countries (Estonia, Hungary, Russia) suggests a much larger

widening of the gap in death rates than in Western European countries (Shkolnikov et al. 2006; Leinsalu et al. 2009).

Life expectancy is shorter in lower socioeconomic groups

As a result of these differences in the risk of dying, people from lower socioeconomic groups live considerably shorter lives than those with more advantaged social positions. Differences in life expectancy at birth between the lowest and highest socioeconomic groups (e.g. manual versus professional occupations, or primary school versus postsecondary education) are typically in the order of 4–6 years among men, and 2–4 years among women, but sometimes larger differences have been observed (Mackenbach 2006). In England and Wales, for example, inequalities in life expectancy at birth among men have increased from 5.4 years in the 1970s to more than 8 years in the 1990s, and remained stable at this high level in the early 2000s (2010). Increases have also been observed in several other countries (Deboosere et al. 2009; Palosuo et al. 2009; Bronnum-Hansen and Baadsgaard 2012; Steingrimsdottir et al. 2012).

Morbidity

Many countries have nationally representative surveys with questions on both socioeconomic status and self-reported morbidity (e.g. self-assessed health, chronic conditions, disability). Inequalities in the latter are substantial everywhere, and practically always in the same direction: persons with a lower socioeconomic status have higher morbidity rates.

Inequalities in generic health indicators

For one indicator, self-assessed health (measured with a single question on an individual's perception of his or her own health), the availability of these data is almost as great as that for inequalities in mortality (Fig. 2.3.2). The overall pattern is clear again: prevalence rates of less than 'good' self-assessed health are higher in lower socioeconomic groups. No clear patterns have emerged in the magnitude of socioeconomic inequalities in self-assessed health between European countries (Cavelaars et al. 1998a, 1998b; Eikemo et al. 2008; Mackenbach et al. 2008).

Beyond early adulthood, socioeconomic differences in self-reported morbidity have been found in all European countries where this has been examined (Cavelaars et al. 1998a, 1998b; Dalstra et al. 2005). For children and adolescents, however, the picture is more mixed. Some studies have suggested that in adolescence, the period between childhood and adulthood, there is a genuine narrowing of health inequalities, perhaps as a result of the transition between socioeconomic position of family of origin and own socioeconomic position. Among children the picture is more consistent: many studies find that parents in lower socioeconomic groups report more ill health for their children than parents in higher socioeconomic groups (Halldorsson et al. 1999).

Inequalities in diseases and disabilities

Socioeconomic inequalities have not only been found for general health indicators, which are usually measured on the basis of self-reports, but can also be found for many specific indicators, including objective measurements of the incidence or prevalence of diseases and disabilities. In the large majority of these studies, higher incidences or prevalences of health problems have been found in the lower socioeconomic groups (Dalstra et al. 2005).

Fig. 2.3.2 Inequalities in self-assessed health in 19 European countries. Note: the graph shows the relative index of inequality, indicating the rate ratio of less-than-good self-assessed health between those with the lowest and the highest socioeconomic position. This is a regression-based measure that takes into account all socioeconomic groups and calibrates the social position of each group to its proportion in the total population.

From the *New England Journal of Medicine*, Mackenbach, J.P. et al., Socioeconomic inequalities in health in 22 European countries, Volume 358, Issue 23, pp. 2468–81, Copyright ©2008 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.

Since the start of the decline of IHD mortality in the 1970s and 1980s, it has been observed that the timing and magnitude of the decline have been different between socioeconomic groups. The decline generally started earlier and has proceeded more rapidly in higher socioeconomic groups, and as a result, people with a lower socioeconomic position currently experience a higher IHD mortality in most industrialized countries (Avendano et al. 2006). In many countries, these inequalities are due to both inequalities in IHD incidence and inequalities in case fatality after myocardial infarction (Salomaa et al. 2000; Stirbu et al. 2012).

Similarly, inequalities in cancer mortality reflect inequalities in both incidence and survival.

Many cancers, particularly those associated with smoking, excessive alcohol consumption, and other lifestyle factors, such as cancers of the respiratory and upper digestive tract, have a higher incidence in the lower socioeconomic groups, whereas risks of cancer of the prostate, breast, ovary, and colon and malignant melanoma are often reduced (Faggiano et al. 1997; Aarts et al. 2010). By contrast, cancer prevalence tends not to be different between socioeconomic groups (Dalstra et al. 2005), perhaps because longer survival of higher socioeconomic status patients ‘compensates’ their lower incidence. Most studies show a survival advantage for patients with a higher socioeconomic position (Kogevinas and Porta 1997), which is at least partly explained by more favourable prognostic factors (e.g. less co-morbidity, more favourable stage at presentation, etc.) (Louwman et al. 2010).

As suggested by data on mortality from suicide (see earlier), mental ill health tends to be more prevalent in lower socioeconomic groups (Fryers et al. 2005; Lorant et al. 2007). The higher prevalence of mental illness in lower socioeconomic groups is likely to have a complex explanation. In psychiatric epidemiology, there is a long tradition of looking at the possible effects of mental health problems on downward social mobility. This ‘drift hypothesis’ has indeed found some support, for example, in the case of schizophrenia, whose onset usually occurs in adolescence and young adulthood, and which may consequently interfere with

school and early work careers. On the other hand, incidence studies have also found higher rates of many mental health problems among those who are currently in a lower socioeconomic position. It seems likely that this at least partly reflects a causal effect, perhaps through a higher exposure to psychosocial stressors and/or a lack of coping resources (Lorant et al. 2007).

As a result of the higher frequency of physical and mental health problems in lower socioeconomic groups, the prevalence of limitations in functioning and various forms of disability also tends to be higher. This applies to many aspects of functioning (mobility, sensory functioning, grip strength, walking speed, etc.) and is particularly evident among the elderly (Avendano et al. 2005). These inequalities in functioning translate into inequalities in limitations with activities of daily living such as dressing and bathing, and limitations with instrumental activities of daily living such as preparing hot meals and making telephone calls. This illustrates the high burden of physical limitations among those with a lower socioeconomic position, and is likely to contribute to substantially higher professional care needs, including institutionalized care (e.g. nursing homes). As suggested by the results for objective measures of grip strength and walking speed, inequalities in self-reported disability are real, and not a matter of reporting bias (Mohd Hairi et al. 2010).

‘Healthy life expectancy’ is shorter in lower socioeconomic groups

We have seen in earlier sections that the higher mortality rates in lower socioeconomic groups lead to substantial inequalities in life expectancy: people in lower socioeconomic groups tend to live between 2 and 8 years less than people in higher socioeconomic groups. The fact that morbidity rates (among those who are still alive) are higher too, contributes to even larger inequalities in ‘healthy life expectancy’ (the number of years which people can expect to live in good health). Inequalities in the number of years lived in good health are often seen of more than 10 years (Sihvonen et al. 1998; Majer et al. 2011).

Costs of health inequalities

Health inequalities do not only represent an enormous loss of human well-being, but also generate economic costs, for example, through excess use of healthcare and social security benefits and through lost labour productivity. Currently, there is no established methodology to estimate these economic costs, but the few studies that have explored this issue have concluded that the economic costs may well be substantial. One study found that the higher rates of health problems among those in the lower half of the socioeconomic distribution account for 20 per cent of the total costs of healthcare, and 15 per cent of the total costs of social security benefits in the European Union (EU), and that the associated losses to labour productivity take 1.4 per cent off gross domestic product each year (Mackenbach et al. 2011). Largely similar findings, interpreted as ‘the costs of inaction’, were reported from a British study (2010).

The facts: explanation

During the past decade, great progress has been made in unravelling the determinants of health inequalities in high-income countries, and here we will summarize the evidence under three headings: “selection” versus “causation”, ‘specific causal pathways’, and ‘overarching ideas’. While we present these explanatory insights for general use, it is important to note that the contribution of each of these factors and pathways differs between countries, even within this relatively homogeneous group. This has been shown decisively for smoking, which is much more important as a determinant of health inequalities in the North of Europe than in the South, but is likely to be true for many other factors and pathways. This is due to the ‘distal’ nature of socioeconomic status: unlike more ‘proximal’ determinants of health like smoking, socioeconomic status exerts its effects indirectly, which leaves a lot of room for interaction with national circumstances.

‘Selection’ versus ‘causation’

Early debates

Early debates about the explanation of socioeconomic inequalities in health focused on the question of whether ‘causation’ or ‘selection’ was the more important mechanism (Macintyre 1980, 1997). Selection explanations imply that health determines socioeconomic position, instead of socioeconomic position determining health. Because of the occurrence of ‘social mobility’ (changes in socioeconomic position during a person’s lifetime) there is ample scope for selection processes: health problems may lead to downward social mobility, and upward mobility may be more likely for those with above-average health. The unspoken assumption in these debates was that selection would be less of a problem for public policy than causation. This assumption was incorrect, however, because limiting the social consequences of health problems is one of the classical objectives of social security and public health policies in many developed countries (Burstrom et al. 2000).

The occurrence of health-related selection is undisputed: during social mobility, some degree of selection on (ill) health does indeed occur, with people who are in poor physical or mental health being more likely to be downwardly mobile (e.g. get a lower status job, or lose income) and less likely to be upwardly mobile (e.g. finish a high level education, or obtain a highly-paid job),

than people who are in good health. Research has shown, however, that the contribution of health-related selection to the explanation of socioeconomic inequalities in health is small, at least when occupational class or education is used as an indicator of socioeconomic status (Bartley and Plewis 1997; van de Mheen et al. 1999). The main reason is that most health problems occur in late middle or old age, after people have reached their final level of education and main occupational status. This is consistent with the fact that longitudinal studies in which education or occupational class have been measured before health problems are present, and in which the incidence of health problems has been measured during follow-up, show clearly higher risks of developing health problems in the lower socioeconomic groups (Marmot et al. 1991; Marmot and Wilkinson 2006).

The conclusion is, however, different for income and wealth as indicators of socioeconomic status. Studies from the United States have found that ‘health shocks’ lead to wealth depletion, partly through medical care costs, partly through income losses due to reduced labour supply, suggesting that these ‘reverse’ effects are actually stronger than the effect of income on health (Smith 1999). Income appears to be much more sensitive to health status than education or occupational class, and in contrast to education and occupational class longitudinal studies that relate income to health outcomes at a later stage have produced inconsistent results (Cutler et al. 2006).

Recent extensions

While the impact of such ‘direct selection’—that is, selection on health or ill health—is likely to be small, particularly when educational level or occupational class is used as an indicator of socioeconomic status, there is more scope for an impact of what has been called ‘indirect selection’—that is, selection on determinants of health. For example, there is some evidence that behavioural risk factors such as obesity affect social mobility, perhaps because of discrimination during recruitment for jobs or promotion (Karnehed et al. 2008; Heraclides and Brunner 2010).

Potentially more important is selection on the basis of personal attributes such as cognitive ability, coping styles, control beliefs, personality, and bodily and mental fitness (Mackenbach 2010). These may influence educational and occupational achievement, and at the same time determine later health, either directly or through health-related behaviours such as consumption and exercise patterns and use of health services. Empirical studies have found associations between many of these personal attributes and social mobility (Atkinson et al. 1993; Judge et al. 1999; Lounsbury et al. 2003), and some multivariate analyses suggest that factors like personality and cognitive ability do indeed contribute to the explanation of health inequalities (Singh-Manoux et al. 2005; Batty et al. 2006; Nabi et al. 2008; Chapman et al. 2010).

This perspective also suggests ways for genetic factors to contribute to health inequalities. Genetic factors do not easily fit into ‘causation’-type explanations, because temporally a person’s genotype precedes his/her socioeconomic status, and a causal effect of the latter on the first is therefore logically impossible. Genetic factors can more easily be seen to operate within a ‘selection’ framework (Mackenbach 2005). An association between socioeconomic status and a certain genotype will arise when the genotype is a determinant of social mobility, for example, through an effect on personal attributes related to social mobility. To the extent that

personal attributes that influence social mobility (cognitive ability, coping styles, control beliefs, personality, bodily and mental fitness, etc.) are genetically co-determined, the underlying genotypes will tend to be more common in the upper or lower social classes (Mackenbach 2005).

Evidence suggests that intelligence and personality profiles are indeed genetically co-determined (Bouchard 1998; Plomin and Spinath 2004), and although their specific genetic determinants have not yet been definitively identified, some role of the genetic determinants of social mobility in the explanation of health inequalities seems plausible. Because of the same social mobility, however, a more direct role of genetic determinants of disease in the explanation of health inequalities is less likely. Research has so far been limited but has not found differences between socioeconomic groups in the prevalence of genetic determinants of disease (Holzapfel et al. 2011).

Disentangling causal effects

Confounding by personal attributes is difficult to get rid of in observational studies, and because experimentation (with random allocation of individuals to higher and lower socioeconomic positions) is impossible, situations have been sought that mimic such experimental manipulation. Lotteries are an example: in lotteries large amounts of money are allocated randomly, and studies have found that the recipients of lottery prizes experience positive changes in self-reported health. These positive effects are particularly seen for mental health and less so for physical health, perhaps because winning a lottery also tends to increase smoking and social drinking (Lindahl 2005; Apouey and Clark 2010).

Similarly, historical changes in the age of compulsory education have been used to study the causal effect of education on mortality. In the United States, between 1915 and 1939, at least 30 states changed their compulsory schooling laws. A comparison

of later-life mortality of children attending school just before and just after the changes took effect showed that 1 year of extra schooling reduced mortality substantially (Lleras-Muney 2002). Such results have also been reported for several other countries (Kippersluis et al. 2011; Lager and Torssander 2012).

Specific causal pathways

The findings summarized in the previous paragraph suggest that socioeconomic inequalities in health at least partly reflect a causal effect of socioeconomic position on health, but the debate on the relative contribution of such causal mechanisms is far from closed. That also applies to the exact nature of these causal mechanisms, which are likely to be largely indirect, by raising the prevalence of specific determinants of morbidity or mortality in lower socioeconomic groups.

Many risk factors for morbidity and mortality are more prevalent in lower socioeconomic groups. Three groups of explanatory factors are likely to explain the bulk of health inequalities in high-income countries: material, psychosocial, and behavioural risk factors. Healthcare may also play a role. Fig. 2.3.3 provides a schematic representation of these mechanisms.

Material factors

There is no doubt that financial resources are very unevenly distributed between people with lower and higher socioeconomic positions, even in high-income countries with strong egalitarian traditions. For example, according to Eurostat, the statistics office of the EU, the 20 per cent of the population with the highest income in the EU-25 received 4.9 times more than the 20 per cent of the population with the lowest income in 2005. The proportion of the population who is at risk of poverty (defined as having an income less than 60 per cent of the national median income) was 16 per cent in the EU as a whole.

Income inequality and poverty rates differ substantially between countries, partly as a result of differences in income taxation and social security schemes. For example, within the EU-25 the ratio of income going to the upper as compared to the lower 20 per cent of the population varied from 3.3 to 8.2 in 2005, and the proportion of the population having an income less than 60 per cent of the national average varied between 9 per cent and more than 20 per cent. Nevertheless, it is quite likely that inequalities in financial disadvantage play an important role in the explanation of health inequalities in all high-income countries.

Financial disadvantage may affect health through various mechanisms: psychosocial stress and subsequent risk-taking behaviours (smoking, excessive alcohol consumption, etc.), reduced access to health-promoting facilities and products (fruits and vegetables, sports, preventive healthcare services, etc.), and so on. Research on the role of the specific contribution of financial disadvantage to inequalities in health is scarce, but as the lowest possible costs for healthy living (as defined by health-based needs for nutrition, physical activity, housing, medical care, social needs, hygiene, and transport) tend to exceed minimum benefit levels (Morris et al. 2007), this role is likely to be substantial.

Variations between countries in income inequality have also been linked to variations in average health: countries and other territorial units with larger income inequalities tend to have lower life expectancy (Wilkinson 1992) and higher rates of mortality and self-reported ill health, even in studies controlling for individual income levels (Kondo et al. 2009). This has been interpreted as indicating a 'contextual effect' of income inequality, which may increase health risks for everyone, perhaps through social comparisons and the resulting psychosocial stress (Wilkinson and Pickett 2009), or through erosion of social capital (Kawachi et al. 1997). It is unclear, however, whether larger income inequalities also go together with larger health inequalities within populations, and the relevance of these findings for explaining health inequalities therefore remains unclear.

Other 'material' risk factors that tend to be more prevalent in lower socioeconomic groups include occupational health risks (exposure to chemicals, accident risks, physically strenuous work, etc.) (Costa and D'Errico 2006), health risks related to housing (crowding, dampness, accident risks, etc.) (Dunn and Hayes 1999), and environmental health risks (air pollution, traffic noise, etc.) (Kruize et al. 2007). Some of these have been shown to make important contributions to the explanation of health inequalities (Marmot and Wilkinson 2006; Siegrist and Marmot 2006).

Psychosocial factors

The second group of specific determinants which contribute to the explanation of health inequalities are psychosocial factors. Those who are in a low socioeconomic position on average are exposed to more psychosocial stressors, in the form of negative life events (loss of beloved ones, financial difficulties, etc.), daily hassles, 'effort-reward imbalance' (high levels of effort without appropriate material and immaterial rewards), and a combination of high demands and low control both in the workplace and beyond (Siegrist and Marmot 2004).

At the same time, they also tend to have smaller social networks, and to have lower levels of social support (Stansfeld 2006), as well as less effective coping styles (Kristenson 2006) and a weaker sense of control over their life and living conditions (Bosma et al. 1999).

This combination of a higher exposure to psychosocial stressors and less capacity to remove or buffer these exposures may explain part of the higher frequency of health problems in the lower socioeconomic groups. This has been best documented for psychosocial factors related to work organization, such as job strain, which have been shown to play a role in the explanation of socioeconomic inequalities in cardiovascular health (Marmot et al. 2006).

Two possible pathways may be involved. The first is a behavioural pathway: psychosocial stress and other unfavourable psychosocial factors increase the likelihood of unhealthy behaviours in lower socioeconomic groups, such as smoking (Droomers et al. 2002), excessive alcohol consumption (Droomers et al. 1999, 2004), and lack of physical exercise (Droomers et al. 1998, 2001). The second is a biological pathway. The experience of stress affects the neural, endocrine, and immune systems of the body, and chronic stress may lead to maladaptive responses in the form of, for example, high blood pressure, a prolonged high level of cortisol, higher blood viscosity, or a suppression of the immune response, which may in their turn increase the susceptibility to a range of diseases (Brunner 1997; Brunner and Marmot 2006; Steptoe, 2006).

Health-related behaviours

The third group of contributory factors are health-related behaviours, such as smoking, inadequate diet, excessive alcohol consumption, and lack of physical exercise. In many developed countries one or more of these 'lifestyle' factors are more prevalent in the lower socioeconomic groups. As we have already seen, many of the disease-specific patterns of health inequalities also suggest a substantial contribution of health-related behaviours to inequalities in mortality.

By far the most widely available data on a specific determinant of health inequalities relate to smoking. In many European countries, particularly in the North of Western Europe, cigarette smoking is the number one determinant of health problems. This is not only because of its role in lung cancer and some other specific diseases, for which it is the main cause. It is also because of its role in (premature) mortality in general, in less than 'good' self-assessed health and in disability, for which smoking is an important contributory factor. The prevalence of smoking differs strongly between socioeconomic groups in many European countries, so one can safely assume that it plays an important role in generating health inequalities (Fig. 2.3.4) (Cavelaars et al. 2000; Huisman et al. 2005b).

In general, the prevalence of smoking is higher in the lower socioeconomic groups, but there are important differences between countries in the magnitude, and sometimes even the direction, of these inequalities. A number of comparative studies within Europe have demonstrated a North-South gradient, with larger inequalities in current smoking in the North of Europe and smaller (sometimes even 'reverse') gradients in the South (Fig. 2.3.4) (Cavelaars et al. 2000; Huisman et al. 2005b). This is particularly clear in the case of women: higher educated women smoke less in the North of Europe (represented by the Nordic countries, Great Britain, the Netherlands, Belgium, etc.), but they smoke more than lower educated women in the South of Europe (represented by Italy, Spain, Greece, Portugal, etc.).

Current rates of smoking are the result of trends which have played out over the past decades: the habit of cigarette smoking started early in the twentieth century with the advent of industrially produced cigarettes, and in many European countries it was

Fig. 2.3.4 Inequalities in smoking and overweight in 19 European countries. Note: the graph shows the relative index of inequality, indicating the rate ratio of current smoking or being obese between those with the lowest and the highest socioeconomic position. This is a regression-based measure that takes into account all socioeconomic groups and calibrates the social position of each group to its proportion in the total population.

From the *New England Journal of Medicine*, Mackenbach, J.P. et al. Socioeconomic inequalities in health in 22 European countries, Volume 358, Issue 23, pp. 2468–81, Copyright ©2008 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.

only after the Second World War that smoking became highly prevalent, first among men (with rates of up to 90 per cent smokers), then among women. In many countries, smoking prevalence has declined over the past decades, at least among men, as a result of health education efforts and other anti-tobacco measures such as raising excise taxes and bans on smoking in public places. This decline in smoking is still continuing, but there have been, and still are, clear socioeconomic differences in this decline (Giskes et al. 2005; Schaap et al. 2008).

While smoking is clearly bad for health, alcohol is a more complex risk factor: both abstinence and excessive alcohol consumption are bad for health (as compared to moderate drinking). Abstinence usually is more common in the lower socioeconomic groups, both among men and among women; however, the pattern

for excessive alcohol consumption is more variable. Many studies report a higher prevalence in lower socioeconomic groups, particularly among men, but the results for women are far from consistent (Droomers et al. 1999, 2004). These inconsistencies may well be due to real differences between countries in the social patterning of excessive alcohol consumption.

In some countries, such as the Nordic countries (e.g. Finland) and several Eastern European countries, ‘binge drinking’ (drinking more than, say, 8 units on a single occasion) is a more serious source of health problems than regular overconsumption of alcohol. In these countries, binge drinking tends to be more common in lower socioeconomic groups, and is likely to contribute to the explanation of health inequalities, e.g. through a higher rate of IHD, stroke, and injury mortality (Makela et al. 1997).

Comparable data on dietary behaviour by socioeconomic status are even more difficult to obtain. The measurement of diet is notoriously difficult, and collecting nationally representative data on diet by socioeconomic position from a range of countries is a costly exercise. Only a few comparative studies have been conducted, and these show that men and women in lower socioeconomic groups tend to less frequently eat fresh vegetables, particularly in the North of Europe. Differences in fresh vegetable consumption are smallest in the South of Europe, perhaps because of the larger availability and affordability of fruits and vegetables in Mediterranean countries. A similar North–South gradient has been found for the consumption of fruits (Cavelaars et al. 1997). Literature reviews have shown that it is likely that many other aspects of diet, such as consumption of meat, dairy products, and various fats and oils, also are socially patterned in many European countries, and that these social patterns differ between countries (Lopez-Azpiazu et al. 2003; Prattala et al. 2003).

Lack of leisure-time physical activity tends to be more common in the lower socioeconomic groups, and so do overweight and obesity. Interestingly, this is one of the very few health aspects where patterns of social variation are clearer for women than for men. Among women, overweight and obesity are more prevalent in lower socioeconomic groups in all countries with available data, with clearly large inequalities in overweight and obesity in Southern Europe (Fig. 2.3.4) (Sobal and Stunkard 1989; Roskam et al. 2010).

The systematic nature of these differences in health-related behaviour clearly demonstrates that these are not a matter of free choice, but must be determined by conditions which are at least partly beyond the control of the individual. Some psychosocial factors that could play a role in generating these behaviour patterns were mentioned earlier. Another possibility is neighbourhood conditions: people with a lower socioeconomic position tend to live in less well-to-do neighbourhoods which may have limited opportunities for physical exercise and purchase of healthy foods (Giskes et al. 2007, 2009; Kamphuis et al. 2007, 2009).

Healthcare

Unequal access to effective healthcare could theoretically also play a role in the explanation of health inequalities. Most high-income countries, however, have healthcare financing systems that have reduced inequalities in access to rather low levels. This is clear from studies of healthcare utilization, which typically show that lower socioeconomic groups tend to use more care than higher socioeconomic groups in accordance with their higher levels of need, and that relatively low use of specialist care in lower socioeconomic groups goes together with relatively high use of primary care (van Doorslaer et al. 2006; Lemstra et al. 2009).

Studies of variations in healthcare outcomes do suggest that there may be inequalities in quality of care that are not captured by studies of global indicators of healthcare utilization. As was mentioned earlier, survival after a cardiovascular event or after a diagnosis of cancer is often shorter for patients in lower socioeconomic groups. Some studies have found higher rates of utilization of surgical and non-surgical interventions among hospitalized patients with a higher socioeconomic position (Hetemaa et al. 2004; Stirbu et al. 2012). Like inequalities in survival after myocardial infarction, inequalities in survival of cancer patients are likely to be partly determined by inequalities in co-morbidity or

other risk factors for mortality independent of care received, but there is some emerging evidence that inequalities in treatment may also play a role, for example, in the case of breast cancer (Aarts et al. 2012).

At the population level, mortality from causes of death that have become amenable to medical intervention also is higher in lower socioeconomic groups. One recent study of educational variations in mortality from amenable conditions in 16 European populations showed that inequalities in mortality from these conditions are often substantial, and contribute between 11 and 24 per cent to inequalities in partial life expectancy between the ages of 30 and 64 (Stirbu et al. 2010). To what extent these inequalities really reflect inequalities in healthcare access or quality is, however, uncertain. Countries with larger inequalities in healthcare utilization have not been found to also have larger inequalities in amenable mortality (Plug et al. 2012).

Overarching ideas

What has emerged from recent research efforts is a rather complex picture of how individuals in the lower socioeconomic strata are exposed over their lifetime to a wide variety of unfavourable and interacting material, cultural, and psychological conditions, and how these exposures lead to ill health—either directly, or indirectly through unhealthy behaviours or psychosocial stress. Various attempts have been made to combine these factors and pathways into overarching theories. We discuss some of these attempts in the following sections.

Life-course perspective

A life-course perspective, which sees the higher rates of illness and premature death among adults and older persons in lower socioeconomic groups as the result of socially patterned exposures acting at different stages of the life course, has proven to be a very useful way of integrating different pieces of evidence. The simplest conceptual model for life course influences is that of ‘accumulation of risk’. Different forms of material and immaterial disadvantage tend to cluster in the same persons, with one disadvantage increasing the likelihood of another one at a later point in time, and studies have found dose–response relationships between measures of cumulative disadvantage and health outcomes (Power and Matthews 1997; Smith et al. 1997).

Such accumulation models can be refined to take into account chains of events reinforcing each other. Interestingly, this also resolves the ‘selection’ versus ‘causation’ debate, because a low socioeconomic position in one stage of the life course may translate into a health disadvantage in the next, which may then lead to a still lower socioeconomic position some years later, and so on. Health-induced downward social mobility then becomes just another form of accumulation of disadvantage (Mheen et al. 1998).

Another type of life-course model focuses on ‘critical periods’, time windows of exposure that are particularly important for health at later ages. One example of such a ‘critical period’ model is the ‘fetal origins of adult disease’ hypothesis. This hypothesis arose when it was seen that low birth weight is not only associated with infant health, but surprisingly also with adult health, e.g. coronary heart disease, stroke, hypertension, and diabetes, probably due to ‘fetal programming’ of growth patterns and related metabolic and endocrine processes (Barker and Robinson 1992). This hypothesis would imply that inequalities in adult cardiovascular

disease may partly be attributable to differences in prevalence of low birth weight and other aspects of early growth, but so far the evidence on this life-course pathway is inconclusive (Power and Kuh 2006).

However, early life influences on inequalities in adult health are not limited to fetal programming of growth patterns. The child's physical, cognitive, and emotional development is strongly influenced by socioeconomic circumstances, and in its turn influences adult health in many ways. Childhood socioeconomic position has an independent effect on adult obesity and smoking, probably because it has a lasting influence on attitudes (Power et al. 2005). Cognitive ability is also shaped by childhood socioeconomic circumstances, and has been shown to mediate the association between childhood socioeconomic position and adult mortality (Hart et al. 2003). Circumstances in early life also set up a pattern of social learning, which may generate a sense of powerlessness reinforced by others in the social network who have been similarly disadvantaged and socially excluded, sometimes over generations (Keating and Hertzman 1999).

Fundamental causes

The theory of 'fundamental causes' stipulates that it is the social forces underlying social stratification which ultimately cause health inequalities, and not exposure to the proximal risk factors which are usually studied by social epidemiologists (like smoking, psychosocial stress, working conditions, etc.). According to this theory, the persistence of health inequalities in different time-periods and different national conditions is due to the fact that a person's socioeconomic status provides him or her with 'flexible resources'. These include 'knowledge, money, power, prestige, and beneficial social connections' which can be used 'to avoid disease risks or to minimize the consequences of disease once it occurs' regardless of the prevailing circumstances. The association between socioeconomic status and health 'is reproduced over time via the replacement of intervening mechanisms', and as opportunities for avoiding disease continue to expand so will health inequalities continue to exist (Link and Phelan 1995; Phelan et al. 2010).

This theory provides an elegant summary of all the more specific explanations, which fail to explain why health inequalities are seen in all countries with available data, and persist over time, regardless of variations in the proximal determinants of health. Although it does not help us to identify the mechanisms underlying health inequalities, it is a useful reminder that in the end the existence of health inequalities depends on the existence of socioeconomic inequalities.

Health inequalities and the welfare state

The persistence of socioeconomic inequalities in health is one of the great disappointments of public health. All countries, including those ranking high on indices of economic prosperity and human development, have systematic inequalities in mortality and morbidity between citizens with a higher and a lower socioeconomic position, as indicated by education, occupation, income, or wealth. This also applies to the highly developed 'welfare states' of Western Europe. All Western European countries have created extensive arrangements aiming to reduce socioeconomic inequality and its various consequences. With notable variations all these 'welfare regimes' include measures to redistribute income (e.g. by progressive taxation and social security)

and a range of collectively financed provisions (e.g. public housing, education, healthcare, access to culture and leisure facilities) (Esping-Andersen 1990).

There is good evidence that welfare policies have contributed to a reduction of inequalities in income, housing quality, healthcare access, and other social and economic outcomes (Esping-Andersen 1990; Kautto et al. 2001), but they have apparently been insufficient to eliminate health inequalities. The explanation of this paradox has puzzled many observers (Huijts and Eikemo 2009; Bambra 2011), and several hypotheses have emerged. Three circumstances may help to explain the persistence of health inequalities despite attenuation of inequalities in material conditions by the welfare state: (1) inequalities in access to material and immaterial resources have not been eliminated by the welfare state, and are still substantial; (2) due to greater intergenerational mobility, the composition of lower socioeconomic groups has become more homogeneous with regard to personal characteristics associated with ill health; and (3) due to a change in epidemiological regime, in which consumption behaviour became the most important determinant of ill health, the marginal benefits of the immaterial resources to which a higher social position gives access have increased (Mackenbach 2012).

The options: how to build a strategy to reduce inequalities in health?

With all these advances in our understanding of health inequalities, we are now in a much better position than, say, in 1980 when the Black Report appeared (Department of Health and Social Services 1980), to develop rational strategies to tackle them. Several European countries have taken steps to develop such strategies, by commissioning evaluation studies of policies and interventions, and by drawing on expert advice to create comprehensive programmes to reduce health inequalities. Bringing together evidence from around the world, the World Health Organization has even called upon all countries to 'close the gap in a generation' (Commission on Social Determinants of Health 2008).

Normative assessment of health inequalities

Reducing inequalities in health, by levelling up the health status of those in lower socioeconomic positions, has thus become an important policy goal in many high-income countries. One reason is technical: potential health gains are larger in lower socioeconomic groups, and raising their health status may therefore be a very effective way to improve average population health. Another reason is normative: health inequalities are widely perceived to be 'unjust'. One particularly striking illustration of this perception can be found in the report of the WHO Commission on Social Determinants of Health, which stated that '[p]utting right these inequities is a matter of social justice. Reducing health inequities is an ethical imperative. Social injustice is killing people on a grand scale' (Commission on Social Determinants of Health 2008).

It is important, however, to first outline the reasoning behind this move from 'inequalities' (a term with ethically neutral connotations, like 'disparities' or 'variations') to 'inequities' (a term which implies that these variations are 'unjust'). This was first done by Whitehead in a simple but effective scheme consisting of two criteria: 'avoidability' (are health inequalities caused by changeable social conditions, and therefore unnecessary?) and

‘unfairness’ (do health inequalities result from conditions out of people’s direct control, not from free choice?) (Whitehead 1992).

According to these criteria, health inequalities caused by exposure to health hazards in the environment, or by restricted access to healthcare, would be considered unjust, as would health inequalities caused by health-damaging behaviour restricted by socioeconomic factors. On the other hand, health inequalities caused by natural biological variation (e.g. genetic factors) or freely chosen health-damaging behaviour would not (Whitehead 1992). Application of this scheme thus requires empirical evidence on the determinants of health inequalities, and on the role of free choice versus ‘conditions out of people’s direct control’—evidence that is actually hard to obtain, although it is hard to imagine that systematic differences in behaviour between socioeconomic groups are based on truly free choice.

Attempts to further formalize the normative assessment of health inequalities have tried to use Rawls’s influential ‘theory of justice’ (Daniels et al. 1999) or Sen’s capability theory (Venkatapuram 2011). The latter theory has become especially popular among social epidemiologists because, in contrast to other theories of justice, it gives a central place to health. It argues that all human beings are entitled to a certain set of ‘capabilities’, such as the ability to live a life of normal length, to have good health, to have emotional attachments to others, and to participate effectively in political decisions. From this perspective, tackling health inequalities should be a central objective of all governments pursuing justice (Venkatapuram 2011).

Policy development vis-à-vis health inequalities

In reality, different countries are in widely different phases of awareness of, and willingness to take action on, socioeconomic inequalities in health. Common milestones in policy development are: high-profile independent reports recommending research or policy on health inequalities; national research programmes on health inequalities; government advisory committees recommending policies to reduce health inequalities; and coordinated government action to reduce health inequalities (Mackenbach and Bakker 2003).

Whitehead has proposed a schematic ‘action spectrum’ to characterize the stage of diffusion of ideas on socioeconomic inequalities in health (Fig. 2.3.5). Starting with a primordial stage in which socioeconomic inequalities in health are not even measured, the spectrum covers the stages of ‘measurement’, ‘recognition’, ‘awareness’, ‘denial/indifference’, ‘concern’, ‘will to take action’, ‘isolated initiatives’, ‘more structured developments’, and ‘comprehensive coordinated policy’ (Whitehead 1998).

Even among high-income countries there are several that find themselves still in a pre-measurement stage. In a country like Greece, for example, data on socioeconomic inequalities in health are almost completely lacking, and awareness of the issue is limited to a small number of academics who do not have structural research funding for studies in this area. Other countries, such as Spain, after a period with heightened awareness due to the publication of high-profile reports, find themselves in a ‘denial/indifference’ stage. Still others, such as France and Italy, are in a ‘concern’ stage: important reports on socioeconomic inequalities in health have been published, and policy-makers are increasingly paying attention to the issue, but real

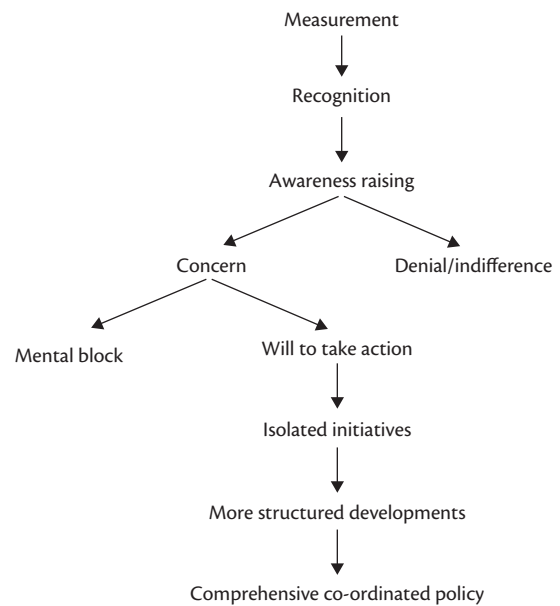

Fig. 2.3.5 Whitehead’s action spectrum.

Reproduced from Whitehead, M., Diffusion of ideas on social inequalities in health: a European perspective, *Milbank Quarterly*, Volume 76, Issue 3, pp. 469–92, Copyright © 1998 Milbank Memorial Fund, with permission from John Wiley & Sons, Inc.

action has not yet been taken. Only a few countries have entered a ‘more structured developments’ stage, with national research programmes as well as high-level advisory committees that have issued comprehensive policy advice on how to reduce socioeconomic inequalities in health, and still fewer have started ‘comprehensive coordinated policy’ (Whitehead 1998; Mackenbach and Bakker 2003).

A rational approach to tackling health inequalities should be based on logical reasoning: dependent on the causes of the problem, and on what is known about possible ways to address these causes, interventions and policies should be developed and tested for effectiveness, and then implemented systematically on the scale required to have population-wide impacts (Whitehead 2007). A possible typology of actions to tackle health inequalities is: (1) strengthening individuals (e.g. improving individuals’ abilities to make healthy lifestyle choices), (2) strengthening communities (e.g. community development initiatives to create healthier conditions in neighbourhoods), (3) improving living and working conditions (e.g. improve access to adequate housing and eliminate work-related health risks), and (4) promoting healthy macro-policies (e.g. reduce income inequalities) (Whitehead 2007).

Within high-income countries, there is considerable diversity in the way scientific evidence is being used to underpin policies to reduce health inequalities. Often, most of the evidence used relates to the contribution of specific factors to the explanation of health inequalities, not to the effectiveness of policies and interventions tackling them (Macintyre et al. 2001). It is only rarely that strategies are developed primarily on the basis of evaluation studies of various intervention options (Mackenbach and Stronks 2004). As we will see in the next section the evidence base is still very limited, and opinion differs on what type of evidence is needed to underpin policies and interventions in this field.

There are those who argue that in view of the urgency of starting to tackle health inequalities ('doing nothing is not an option') (Petticrew et al. 2004), one should be prepared to start intervening on the basis of plausibility. Political 'windows of opportunity' are usually short, for example, 4 years at most, and they may be closed before careful evaluation studies have been conducted (Whitehead et al. 2004). A parallel has been drawn with nineteenth-century public health interventions for which controlled intervention studies have never been done, but which were implemented on the basis of plausibility and have proven to be highly successful (Davey Smith et al. 2001). Under the pressure of politicians wanting to see rapid results, the best that can be achieved in terms of scientific evaluation may then be large-scale implementation accompanied by a 'real-time' evaluation study of the intervention, concurrent with its implementation, using some quasi-experimental design (before–after study, interrupted time-series study, and so on) (Macintyre 2003).

On the other hand, there are those who argue that this is a strategy with serious risks. Like in other areas of social and health policy, the actual results of policies and interventions to reduce health inequalities could easily be counterintuitive. There are many historical examples of 'plausible' interventions and policies that did not work, or actually had adverse effects (Macintyre et al. 2001). In addition to that, one could argue that any investment in reducing health inequalities should be justified on the basis of a comparison of its cost-effectiveness with that of other possible investments in health and well-being, and that producing credible evidence is therefore essential (Oliver 2010).

Another issue for debate is what types of evidence are best suited to underpin policy decisions in this area. Clearly, randomized controlled trials will not always be feasible, particularly for the evaluation of policies and interventions that are applied on a population-wide scale. Sometimes, community intervention trials, in which groups of people (school classes, neighbourhoods, etc.) instead of individuals are allocated to the intervention and control condition, will then be a good alternative. But in many circumstances one will have to rely on quasi-experimental or even observational designs to inform policymakers on the effectiveness of new approaches. Controlled before–after studies or interrupted time-series designs could then be used, or observational studies of 'natural experiments', for example, by making comparisons between countries (Thomson et al. 2004). Useful guidance has been developed to support further research in this area (Craig et al. 2008, 2011). Also, a Cochrane and Campbell Equity Methods group has been set up to ensure that research about differential effectiveness of health interventions is available worldwide (<http://equity.cochrane.org/>).

A complicating factor in evaluating the effectiveness of policies and interventions to reduce health inequalities is that this effectiveness should be measured in terms of favourably changing the distribution of health problems in the population, not of reducing the rate of health problems in a particular group. A 'full' study design therefore requires the measurement, in one or more experimental populations and one or more control populations, of changes over time in the magnitude of health inequalities. Any other design, such as an experimental study of changes over time in the rate of health problems in lower socioeconomic groups only, requires rather strong assumptions to be made, in this case

on the absence of health effects in higher socioeconomic groups (Mackenbach and Gunning-Schepers 1997).

Innovative approaches

A number of innovative approaches to reduce health inequalities have been developed, for which there is at least some empirical evidence suggesting that they can help to reduce health inequalities (Mackenbach and Bakker 2002). A few examples are discussed here.

Health inequalities are partly due to labour market and working conditions. Swedish labour market policies enforce strong employment protection and active promotion of labour market participation for citizens with chronic illness. A comparison with England suggests that these policies have been effective in protecting vulnerable groups from labour market exclusion during the recession of the 1990s (Burstrom et al. 2000). In France, occupational health services are mandatory and include an annual health check for every employee. This provides a good setting for introducing preventive activities for those who otherwise have few medical contacts, particularly those in manual occupations. Randomized controlled trials within this setting have shown that interventions aimed at detection and treatment of hypertension and smoking cessation were successful (Lang et al. 1995, 2000). Improvements of working conditions have made important contributions to reducing health inequalities in the past, but a lot remains to be done. In the Netherlands a recent intervention study suggests that task rotation among garbage collectors reduces sickness absenteeism. Rotation of tasks (truck driving and minicontainer loading) reduces physical load and possibly also increases job control (Kuijer et al. 1999).

Health-related behaviours like food consumption, smoking, and physical exercise also contribute to socioeconomic inequalities in health. Finnish nutrition policies have followed the Nordic welfare ideology where universalism has been the general principle. School children, students, and employees in Finland receive free or subsidized meals at school or workplace, and special dietary guidelines have been implemented ensuring the use of low-fat food products. This has probably contributed to the favourable trend of narrowing socioeconomic inequalities in use of butter and high-fat milk in Finland (Prattala et al. 1992). In many countries, smoking is increasingly concentrated in lower socioeconomic groups, and reviews show that a variety of policies and interventions is effective in reducing smoking in these groups. Whereas the price weapon (raising excise taxes) is very effective, its regressive impact on the poorest smokers who cannot stop should be counteracted by active promotion of the use of nicotine replacement therapy and other cessation support. A national programme which created smoking cessation services in disadvantaged areas in England has effectively reached disadvantaged smokers and reduced the gap in smoking somewhat (Bauld et al. 2007).

Despite these and many other advances, however, the evidence base for tackling inequalities in health remains thin. An 'umbrella review' of social interventions covering housing, work, transport, unemployment, food, and education showed that differential impact on socioeconomic groups was only occasionally studied. Only in the case of work interventions did the authors see some evidence for an effect on reducing inequalities (Bambra et al. 2010). A similar 'umbrella review' of smoking interventions

covering price increases, access restrictions, and smoking bans only found evidence for an inequalities-reducing effect of price increases (Main et al. 2008). Evidence-based policymaking to reduce health inequalities therefore remains a great challenge.

Comprehensive strategies

As it is unlikely that any single policy or intervention will significantly reduce socioeconomic inequalities in health, ‘packages’ of policies and interventions of a more comprehensive nature have been devised by government advisory committees in Britain, Sweden, the Netherlands, Norway, and Finland.

Britain

The Black Report, commissioned by a Labour government to investigate the causes and possible remedies for Britain’s undiminished social class inequalities in mortality, had proposed a radical change in social and healthcare policies but had disappeared in a desk drawer after the Conservatives won the 1979 elections (Department of Health and Social Services 1980). However, research continued and when Labour came back into power almost 20 years later, it again commissioned an expert report to bring together all the evidence—the Independent Inquiry into Inequalities in Health (Department of Health 1998)—and developed a comprehensive programme to tackle health inequalities.

This programme consisted of a range of new government policies including the introduction of a national minimum wage, higher benefits and pensions, and substantially increased spending on education, housing, urban regeneration, and healthcare. It also announced a number of specific initiatives including the ‘Sure Start’ programme (free child care, early education, and parent support for low-income families), ‘Health Action Zones’ (local strategies to improve health in deprived areas), and a series

of anti-tobacco policies (including free nicotine replacement therapy for low-income smokers) (Department of Health 1999). In a further evolution of the programme two quantitative targets (to narrow the socioeconomic gap in life expectancy and that in infant mortality by 10 per cent in 2010) were added, and priority was given to key interventions expected to contribute to closing the life expectancy gap, such as reducing smoking in manual social groups, managing risks for coronary heart disease and cancer (poor diet and obesity, physical inactivity, hypertension), and reducing accidents at home and on the road (Department of Health 2003). The total budget exceeded £20 billion (Table 2.3.2).

The strategy came to an end with the 2010 parliamentary elections and the formation of a Conservative/Liberal Democrat coalition government. An extensive review of the achievements of the programme showed that it had been a mixed success: despite positive effects in some areas (e.g. reduction of child poverty, improvements in housing, better uptake of influenza vaccination) most indicators showed a widening instead of a narrowing of health inequalities, and the programme missed its targets (Department of Health 2010). Further analyses showed that the failure to achieve the targets was due to the fact that the strategy had not sufficiently focused on the most relevant entry-points, that effective policies were unavailable at that point in time, and that the scale of implementation had not been sufficient for achieving population-wide impacts (Mackenbach 2011).

Other European countries

Despite its partial failure, the British programme has set an extremely valuable example that deserves to be followed elsewhere. Its combination of an evidence-based approach (choosing entry-points on the basis of scientific evidence, and regular monitoring to keep track of progress) with a strong implementation

Table 2.3.2 The English programme to tackle health inequalities: commitments and their achievement

‘Departmental commitments’	Examples	Budget (2004–2007) ^a	Direct relevance for life-expectancy target	Direct relevance for infant-mortality target	Commitments mostly met (2007) ^b
Maternal and child health	Sure Start, chikcare, Welfare Food Scheme	>£2 billion	No	Yes	Yes
Improving life chances for children	Mental health, sports facilities, education	>£2 billion	No	No	Yes
Reducing teenage pregnancy	Sex education, care access	Not specified	No	Yes	Yes
Engaging communities	Neighbourhood Renewal, homelessness reduction	>£1.5 billion	No	No	Yes
Prevention	Smoking cessation, 5 A Day, injury prevention	Not specified	Yes	No	Yes
Primary care	Facilities, breast cancer screening, flu immunization	>£1 billion	Yes	No	Yes
Effective treatment	Access to cancer services, access to coronary-heart-disease services	>£0.5 billion	No	No	Yes
Underlying determinants	Child poverty, fuel poverty, Pathways to Work	>£15.5 billion	No	No	Yes

plan (clear commitments shared between government sectors, and supported by serious budget allocations) has so far not been matched elsewhere.

In the Netherlands a national 'Program Committee on Socioeconomic Inequalities in Health' issued a set of 26 specific recommendations in 2001. The recommendations were partly based on a series of intervention studies in which 12 different interventions addressing specific inequalities in health were evaluated. Examples of recommendations include 'no further increase in income inequality', 'no cuts in disability benefits', 'increase labour participation of the chronically ill', 'reduce physically demanding work', 'increase tobacco taxation', 'implement school health policies' and 'strengthen primary care in deprived areas' (Mackenbach and Stronks 2002). Due to changes and instability in the composition of national governments in the Netherlands, the recommendations have so far not been followed. At the local and regional level, however, many new initiatives have been taken to tackle health inequalities (Mackenbach and Stronks 2004).

Several of the Nordic countries have also developed comprehensive strategies to reduce health inequalities. In Sweden the National Public Health Commission, a committee consisting of representatives of all political parties, scientific experts, and advisers from governmental and non-governmental organizations, has developed a new national health policy with a strong focus on reducing health inequalities. It further involved extensive consultation of numerous organizations, and the proposal itself includes action by a wide range of actors in society. The commission formulated 18 health policy objectives grouped in six large areas: strengthening social capital, growing up in a satisfactory environment, improving conditions at work, creating a satisfactory physical environment, stimulating health-promoting life habits, and developing a satisfactory infrastructure for health (Swedish National Institute of Public Health 2005). So far, the results of national programmes to tackle health inequalities in Sweden and the other Nordic countries have not been systematically assessed.

Conclusion

Whether it will actually be possible to substantially reduce socioeconomic inequalities in health remains an open question. The good news, however, is that there has been enormous progress in explanatory research, and that this has identified a large number of targets for policies and interventions to tackle health inequalities. There has also been a beginning of research and development for effective interventions and policies to tackle health inequalities. While this is still a modest beginning, it does put us in a better position to reduce socioeconomic inequalities in health in the coming decades. A number of innovative approaches have been developed for which there is at least some evidence of effectiveness. Comprehensive packages have been developed in several countries that have a sound theoretical basis and clear inspirational value.

Developing effective strategies to reduce health inequalities is a daunting task. No single country has the capacity to contribute more than a fraction of the necessary knowledge. This is a matter not only of restricted manpower or financial resources for research, but also of restricted opportunities for implementing and evaluating policies and interventions. Some policies can be implemented and evaluated in some countries and not in others, either because they have already been implemented or because

they are politically infeasible. International exchange is therefore necessary to increase learning speed.

Reducing health inequalities in developing countries

Hoosen Coovadia and Irwin Friedman

Introduction: why is health inequity an issue?

Well-being is profoundly impacted by many social and economic determinants. Clearly, access to basic needs such as food, water, shelter, education, decent employment, safe working conditions, and so on are crucial to health. But even many higher-order needs such as social inclusion, involvement in governance issues such as policy development (e.g. on human rights and gender equity), the right to critique unfair administration, or participate in the exercise of political power are also important. Indeed, well-being is so tightly linked to the broad ecology of social determinants, it has become increasingly evident that the health of a population is fundamentally dependent on fair access to social goods and processes within the society. Health equity and social justice are interlinked. Well-being depends on fairness (McKeown 1976; Acheson 2000; Deaton 2003; Wilkinson and Marmot 2005). While the insight may not be new, what is of contemporary relevance is that the causes of health inequity, once thought to be beyond the realms of intervention, are now routinely being considered for inclusion within the parameters of progressive health programming. Close examination of the evidence by expert groups has indeed shown that effective interventions to address injustices in the socio-economic conditions underpinning health are not only possible, but warranted. Where avoidable systematic disparities in health occur in situations which could be avoided by reasonable, timely action, then they can be judged as unfair. This unfairness can be labelled as health inequity. These insights formed the basis for the conclusions and recommendations of the Commission for Social Determinants of Health (CSDH) (CSDH 2008), which are discussed in some detail in the following sections.

Definition

Health equity relates to the fairness in distribution of health resources and outcomes. This applies both to equity between citizens in specific countries (intra-country) as well as between countries (inter-country) or regions (inter-regional). The World Health Organization (WHO) defines health inequalities as ‘differences in health status or in the distribution of health determinants between different population groups’ (Quigley et al. 2006; WHO n.d.). Putting right these inequities—the huge and remediable differences in health between and within countries—is a matter of social justice, founded on the linked concepts of fairness, justice,

and freedom. These ideas echoed the sentiments of strong equity advocates such as Amartya Sen (Sen 1999), who for many years had argued that freedom from poverty, social deprivation, political tyranny, and cultural authoritarianism was crucial if the social and economic development to which all countries aspire was to be achieved. Inequity was anathema for socioeconomic well-being. Development was therefore dependent on social justice, founded on a system of supportive institutions and all citizens having access to basic education and essential health. For John Rawls (Rawls 1958), justice is fairness.

Absolute and relative health inequalities and socioeconomic status

There are health inequities everywhere, but they are more pronounced in certain settings. Rather than viewing this in terms of absolute differences between rich and poor they should be understood as comprising relative social gradients. It follows that where societal resources are maldistributed by elements such as income, class, spatial location, race, and gender, population health will correspondingly be unequally distributed. Interventions to deal with these are discussed in the section entitled ‘Tackle the inequitable distribution of resource and power’.

Improving health inequalities by addressing social determinants

One of the earliest attempts to understand health inequity dates back to the work of Edwin Chadwick, a leading figure in the effort to investigate and combat the considerable differences in health that existed in nineteenth-century Britain. Documented in his famous report on *Enquiry into the Sanitary Condition of the Labouring Population of Great Britain and the Means of its Improvement* (Chadwick 1843) was a description of the awful living conditions endured by the poorest in society compared to those that were relatively well off (Table 2.4.1). The findings of his report helped pave the way for the introduction of the Public Health Act of 1848 in Britain.

Despite progress in public health for more than a century and a half, even in developed countries such as Britain, health inequalities continue to persist. Unsurprisingly they present among the biggest of global health challenges.

One of the most significant efforts to counter health inequalities was the ‘Health for All’ (HFA) programme of the WHO, which

Table 2.4.1 Key finding of Edwin Chadwick’s report

	Average age of deceased
<i>Liverpool 1840</i>	
Gentry and professional persons	35 years
Tradesmen and their families	22 years
Labourers, mechanics, and servants	15 years
<i>Bath 1840</i>	
Gentry and professional persons	55 years
Tradesmen and their families	37 years
Labourers, mechanics, and servants	25 years

Reproduced from Edwin Chadwick, *Report on the Sanitary Condition of the Labouring Population of Great Britain: A Supplementary Report on the results of a Special Inquiry into The Practice of Internment in Towns*, printed by R. Clowes and Sons, for Her Majesty’s Stationery Office, London, UK, 1843.

was based on the 1978 Alma Ata Declaration, which set out the principles of primary healthcare (PHC). This approach introduced a radically new equitable approach to the provision of health services which was of particular relevance to developing countries. During the 1980s this approach became the impetus for health activities based on addressing the range of factors impacting on well-being. Increasingly the social and economic determinants of health became a focal point of HFA programmes (WHO 2003). There were setbacks, however, when a downturn in global economic conditions, accompanied by adverse conditions in developing countries, slowed and in some cases, reversed progress. Sadly, despite growing attention, increased global funding as well as innovative programming, the problem of inequity in health systems is little better. In fact, despite the considerable efforts to achieve the Millennium Development Goals (MDGs), the prospects of achieving these by 2015 is unlikely. A new paradigm is needed to deal with the powerful forces that have shaped and will continue to shape the world health scene. Without such a change, inequity and health injustice will persist (Gostin 2012).

Quite what a new post-MDG framework focused on global health justice will look like is not yet clear, despite the attention that the issue is receiving from many groups. One example of a promising approach, however, is that being pursued by the Joint Action and Learning Initiative on National and Global Responsibilities for Health (JALI). As a global coalition of civil society and academics, JALI is championing an international campaign of advocacy for a Framework Convention on Global Health (FCGH). Its approach includes novel ideas such as defining both national and international responsibilities to improve health equity by setting global health priorities and arguing for reliable, sustainable funding; overcoming fragmented activities; reshaping global health governance; and providing strong global health leadership through the WHO (UN Millennium Project 2005).

The WHO Commission on Social Determinants of Health

In an effort to address the social, economic, and environmental conditions that impact on health and cause health inequity, in 2005, the WHO established the Commission on Social

Determinants of Health¹ (CSDH) to provide context-specific advice for regions, countries and global health partners (Gostin 2012; The Commission on Social Determinants of Health Knowledge Networks 2011).

Some novel WHO activities have grown out of the insights of the CSDH and several are now global initiatives. The three focal areas of the CSDH findings are to: (1) improve daily living conditions, (2) tackle inequality in the distribution of resources and power, (3) understand and measure the extent of health inequity and take action.

These three focal areas have become the pillars for reducing health inequities, which may require attention in several dimensions such as equality of rights and opportunities as well as equity in living conditions to achieve fairness in distribution.

Improve daily living conditions

Promote equity from conception

Child development begins with the health of the mother during pregnancy. Once born, many factors may affect the child in its physical, social, emotional, linguistic, and cognitive milieu. All of these critically influence the growth, development, and health of the child. Any may influence the child’s life chances and affect well-being, education, and occupational opportunities. In turn, such factors affect diverse risks of individual propensity to obesity, malnutrition, mental health disorders, cardiovascular diseases, and criminality.

The evidence suggests that pre- and postnatal interventions reduce health inequalities and improve maternal and child health outcomes, particularly if these are aimed at the poorest quintiles in low- and middle-income countries (Carrera et al. 2012; Chopra et al. 2012; Countdown 2012 Report Writing Group 2012).

Provide a more equitable start in early life

A comprehensive approach to early life, built on the experience of existing child survival programmes, but including also early learning activities to stimulate social/emotional and language/cognitive development is important. Increased coverage of high-impact child survival interventions such as skilled birth attendants, measles vaccination, treatment of childhood diarrhoea and pneumonia, provision of insecticide-treated bednets for children, offering nutrition support, and introducing appropriate socioeconomic measures can all have these effects. The outcomes may reduce neonatal morbidity as well as longer-term reductions in stunting and underweight (Amouzou et al. 2012; Victora et al. 2012).

Create healthy places for people

The environments where people live and work profoundly affect their lives and well-being. Taking action to promote fair planning and improving habitats in both rural and informal urban areas through proactive town planning is essential for long-term health equity. Sustained investment in rural development, removing exclusionary policies and processes that lead to rural poverty, dealing with landlessness, and reducing the displacement of people from their homes are all measures that improve the settings in which people live and work. Climate change and other policies or programmes to prevent environmental degradation should also take health equity into account.

Meaningful employment and decent work

Unemployment is one of the major determinants of health inequity.

Meaningful employment and work opportunities for disadvantaged populations profoundly affects health equity. When people have jobs they value the opportunity for work as this boosts their self-esteem and provides financial security. This in itself may be a prerequisite to self-development, enhancement in social standing, and better relationships both within the family and society. Working people are less vulnerable to physical dangers and societal hazards such as alcohol dependency. Unemployment, precarious employment, indecent work, or poor working conditions can result in the opposite with damage to self-esteem, and exposure to a variety of social ills including the need to engage in transactional sex, sell or use drugs, or resort to crime.

Actions to make full and fair employment, as well as decent work, the cornerstones of national and international social and economic policymaking are crucial to achieving health equity. Improving working conditions for all workers reduces accidents, minimizes harmful exposures to material hazards, decreases work-related stress, and diminishes health-damaging behaviours. If health equity is to be achieved, safe, secure, fairly paid, all-year-round work opportunities, and a sound work-life balance are basic needs for all citizens.

Social protection throughout the full life cycle

People of all ages, whether they are infants, toddlers, children, adolescents, young people, working adults, or older persons, need social protection. Everyone is at all times vulnerable to adverse life events which can strike even those who are well endowed. Especially during periods of grave disturbances in their lives such as catastrophic diseases, disabilities, and unemployment, social protection is important.

All governments should be proactive in creating social protection policies that mitigate the impacts of life-disturbing events that may affect individuals.

Comprehensive social protection should include the public provision of basic utilities such as free or low-cost water, sanitation, electricity, housing services, as well as education, health, and welfare services. Provision of such public goods and services, also known as the social wage, comprises the building blocks of a fair and just society.

Universal healthcare

The health system itself can be considered a social determinant of health. While a good system with a well-trained, capable, and motivated workforce can improve health equity, a poor system may make things worse by imposing costs through out-of-pocket expenses without offering sufficiently good care. This can delay or deny health services and may also aggravate poverty. To deal with this, the action that is necessary is for governments to strive to provide universal health coverage of sound quality based on the principles of PHC. This would include the provision of equitable, accessible, appropriate, affordable services focused on health promotion, disease prevention, and multi-sectoral social development in which citizens are active participants.

Tackle the inequitable distribution of resources and power

Health equity in policies and programmes

All dimensions of societal activity, the economy and finance, education, sanitation, housing, transport, employment creation,

and so on, have the potential for affecting health and well-being of the population and individuals. Socioeconomic status (SES) and health are associated across a continuous gradient at all levels (Alder et al. 1994), and not just at the extremes of wealth and poverty. This relationship is true whether measured as income, employment, education, residential environment, social status, occupation, or other stratifications. Action requires placing responsibility for action-on-health and health equity at the highest level of government, to ensure its coherent implementation across all policies. This requires that ministries of health adopt a social determinants approach and develop a framework across all of its policy and programmatic functions. Indeed, ministries of health should become champions advocating adoption of the social determinants approach across government. Where such attempts at coherence are being made in developing countries, as described later under 'National health insurance and universal coverage', there has been opposition from many vested interests, such as the private sector, pharmaceutical companies, international corporations with investments in developing countries, and right-wing social groups. The lack of will by governments in the developing world, often buttressed by demands of their elites, exacerbates the implementation of socially just public health programmes.

Many health indicators such as standard mortality ratios, annual death rates, and infant mortality are strongly correlated with SES, even though the full explanation underlying the environmental, biological, psychosocial, and behavioural mechanisms that explain this association are not fully understood (Alder et al. 1994) (Fig. 2.4.1).

In the past researchers usually simply controlled for SES rather than attempting to change it. And even today, only the effects on lower, poverty-level SES are generally examined. Excessive wealth, for example, is not considered a problem. There might, however, in the light of recent findings, be good reasons to undertake wealth studies to supplement those on poverty and to demonstrate that greater equity is beneficial for all, even the wealthy (Wilkinson and Pickett 2010). This observation requires that fresh thinking and novel approaches about the domains through which SES may exert its health effects are needed.

Adopting the health equity paradigm requires rephrasing of commonly asked questions which challenge the structural issues underpinning inequity to shift the burden away from its 'victims': 'How can we promote healthy behaviour?' by 'How can we target dangerous conditions and reorganize resource use and public policies to ensure healthy spaces and places?'. Instead of 'How can we reduce disparities in the distribution of disease and illness?' ask instead, 'How can we eliminate differentials in the distribution of power and resources that shape health outcomes?'. Similarly, we could ask 'What types of institutional and social changes are necessary to tackle health inequities?' and 'What kinds of alliance building and community organizing are necessary to mobilize and protect communities?'. This different paradigm recognizes that structural social, economic, historical, and ideological factors play a fundamental role shaping health outcomes and in the increasing health inequities that characterize many aspects of the global landscape.

There is considerable empirical evidence that health inequities are growing between the advantaged and marginalized, wealthy and poor, both within and between different countries (Dahl et al. 2002) as well as global regions (Kahn et al. 2000; Lochner et al. 2001; Deaton 2003; UC Atlas of Global Inequality 2007).

Fig. 2.4.1 The negative association between socioeconomic status (horizontal axis) and mortality indicators (vertical axis) (Alder et al. 1994).

Source: data from Alder NE et al., Socioeconomic status and health: The challenge of the gradient, *American Psychologist*, Volume 49, Issue 1, pp. 15–24, Copyright ©1994.

The greater the differences in health between social groups within a society or between countries the steeper the gradient or the greater the inequity (WHO 2003). This relationship between an Index of Health and Social Problems and Income Inequality has been extensively documented (Wilkinson and Pickett 2006, 2010, figure 13.1; Inequality.org 2012).

The relationship between longevity and healthcare spending in the public sector, in selected countries, at varying levels of development, is shown in Fig 2.4.2 (UC Atlas of Global Inequality 2007). Levels of development are clearly linked, unsurprisingly, to life expectancy. As important, is the group of countries (ringed) which gain years of longevity similar to those reached by the upper income countries but at much lower cost. Similar graphs with a wider spread of countries are available from the UC Atlas of Global Inequality (2007).

It is clear that above a certain threshold of health expenditure there is no commensurate benefit in life expectancy, as dramatically illustrated by the differences between high expenditures in the United States and far lesser expenditures in Singapore and Cuba. There are also discrepancies if one considers only averages. One reason for the discrepancy is that these averages mask inequalities. Nevertheless, it is clear that disparities within countries explain the outliers as shown in the comparison of the following Gini² coefficients (Central Intelligence Agency 2009). South Africa (Gini 65 per cent in 2005), for example, which has very high levels of inequity, has low levels of life expectancy (Weissman 1999). In comparison, Cuba (Gini 30 per cent) and Singapore (Gini 47 per cent), which have a much lower level of inequity, correspondingly have life expectancies that are as high as the wealthiest countries. And extreme wealth does not guarantee equity. For example, in the United States (Gini 45 per cent), despite the clinical excellence of its private health services, millions of Americans lack basic health insurance, and are therefore less likely to receive preventive care. In contrast, Cuba, despite its limited resources, and many economic problems, has achieved a similar longevity in its population by prioritizing the provision of universal health. It has, despite its evident lack of resources, even created very high doctor-to-patient ratios.

Fair financing

Public financing for the social determinants of health is fundamental to the promotion of health and prevention of disease. Public financing and the progressive achievement of universal coverage in the developed world has historically led to socioeconomic progress. Accepting that there is market failure (as, for example, in the United States), in the delivery of equitable health services and the prevention of certain diseases (public goods), public finance is therefore necessary to ensure universal access to health. As a result, strong public sector leadership and adequate budgets are the foundations of an equitable health system. Action is required to strengthen public finance for action on the social determinants of health. It means that national governments fairly allocate tax resources for implementation of the social determinants of health. A national health insurance, as one of the components of social spending, funded from progressive taxation and from other sources, should become the cornerstone of redistributive policies aimed at counteracting health inequity and reducing poverty. This is necessary at country level, but important also globally. Increased international finance for health equity, coordinated through a 'social determinants of health action framework', is as important as redistribution at a national or regional level. The United Kingdom, Australia, Canada, Italy, New Zealand, and Sweden are examples of developed countries in which general taxes are the main source of public funds for health services (National Audit Office 2003). In middle- and low-income countries there are several examples as well. Thailand (Evans et al. 2012), Israel (Cohen 2012), Taiwan (Chiang 1997; Cheng 2003; Lu and Hsiao 2003), Mexico (Anonymous 2012), Trinidad and Tobago (Tsountal 2009), and Chile (Government of Chile 2005) also have publicly funded schemes that provide universal access.

Market regulation

Using an unfettered market-orientated approach to health development is a double-edged sword. While it may assist with introducing new technologies and services which provide some benefit, it is as likely to cause unintended consequences in creating unnecessary or unhealthy goods and services, exacerbating unhealthy

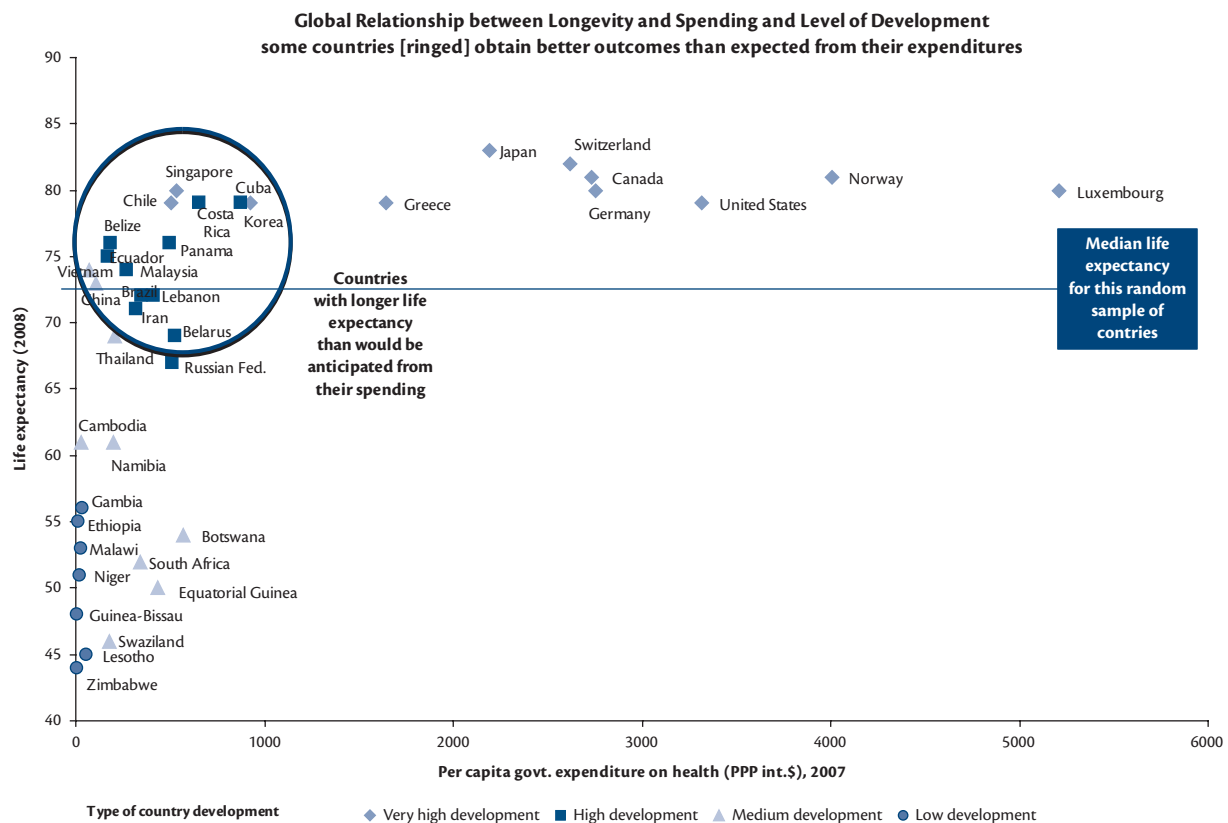

Fig. 2.4.2 The parabolic relationship between per capita healthcare spending (horizontal axis) and life expectancy (vertical axis) showing a plateau at about US \$500 per capita.

working conditions, and increasing health inequity by serving mainly those with financial resources.

At the international level, the World Trade Organization's Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) provides a case in point. While efforts to protect the intellectual property rights of innovating companies has encouraged investment in drug discovery, the creation of the 20-year patent for new drugs has meant that many poor people have not been able to afford them and therefore access to novel medicines in poor countries has been limited. This contradiction was brought to the fore in the late 1990s when life-saving antiretroviral drugs were initially denied to those in developing countries because of the unreasonably high costs of the drugs. This led to an intense struggle against injustice. Although vigorous global advocacy eventually forced concessions from patent holders, TRIPS remains. Health equity in respect of access and availability to medicines will be severely challenged until there is greater flexibility or elimination of this restriction (Gwatkin and Ergo 2011; Latko et al. 2011).

Responsible governments should take steps to introduce some degree of market regulation to enable the realization of the benefits of free enterprise, while limiting the damage that could exist in a free-for-all situation. It remains important for governments to continue to play an active role in the provision of basic services essential to health (such as water, sanitation, housing, and education) and the regulation of goods and services with a major impact

on health (such as medicines, medical devices, alcohol, tobacco, and food).

Gender equity

Gender inequities, characterized by harmful masculine norms, pervasive in almost all societies, impact significantly on child health and survival. The uneven power relationships, resources, entitlements, norms and values, as well as the way in which organizations are structured, and programmes are run, although they impact mostly on girls and women also have serious consequences for boys and men. There are innumerable ways that gender impacts on inequity whether as a result of unfair feeding patterns, violence against women, unfair divisions of work, leisure, and opportunities to improve life as well as inequitable decision-making. This ultimately leads to poor access to health resources. Profound as these gender inequities are, they are socially generated and therefore can be changed. Interventions to counter this require that the gender biases in the structures of society be challenged and new norms established in the formulation of laws and their enforcement. Also important is to reorganize the way institutions are run. Creative rethinking is necessary in regard to the development of national economic policies to close the gaps in education and skills development such that they are supportive of female economic participation. Greater spending on sexual and reproductive health services and programmes as part of universal coverage and rights are very important.

Political empowerment

Democratic participation in a full and unrestricted manner is a very important aspect in creating an equitable society which is free of material and psychosocial deprivation. Exclusion from participatory processes is one of the key dimensions that adversely affect well-being. People's movements and community empowerment initiatives can mitigate exclusionary social practices. Ultimately, however, although civil society and the private sector can support policies which advocate for active social inclusion, it is the government that has to adopt legislation that will guarantee citizen rights to participation. Action steps to improve this require that all groups in society be empowered to participate in democratic, participatory processes. Inclusive social practices enable civil society organizations to promote political and social rights in a way that improves health equity.

Good global governance

The huge disparities between the lives and health of people in different parts of the world are a reflection of the unequal distribution of power and wealth of different countries. While there are benefits to globalization, there are also severe consequences for the poor and this has highlighted the need for the WHO's efforts to strengthen multi-sectoral action for development and improve global leadership to take proactive steps to tackle the social determinants of health and to institutionalize these efforts as a guiding principle.

Measure and understand the problem and assess the impact of action

The social determinants of health: monitoring, research, and training

Reliable data are essential to identify health problems and devise solutions to factors impacting the social determinants of health. This requires: ensuring that routine monitoring systems for health equity and the social determinants of health are in place, locally, nationally, and internationally; investing in generating and sharing new evidence on the ways in which social determinants influence population health equity; and on evaluating the effectiveness of measures to reduce health inequities through action on social determinants.

Differences of SES can be measured in two main ways: individual household measures and geographic/area based measures, each with advantages and disadvantages.

Individual measures use indicators such as income (personal or individual), educational levels, or occupation. Although the value of these is their specificity, often such information is not generally available. Within countries the income inequities between the top 20 per cent and the bottom 20 per cent of the population can be used for this purpose.

Geographic-based information relates to areas and although not applicable to all individuals can be applied to a group of people.

South Africa—an example measuring extreme inequality

Measuring changes in such inequalities is of great importance in monitoring and evaluating programmes designed to ameliorate this.

South Africa has the worst global indicators of inequality. One example of an approach to measure this is charting the relative deprivation of populations across districts within the country as

developed by a South African non-governmental organization, the Health Systems Trust (Day et al. 2011). It ranks districts in relation to a Deprivation Index (DI) derived from a set of demographic and socioeconomic variables (see list) obtained from national General Household and Community Surveys, which are generally available in the country. These surveys provide measurements of various indicators of vulnerability:

- ◆ Under-5 population.
- ◆ Black Africans as a proportion of the total population.
- ◆ Female-headed households.
- ◆ Household heads with no formal education.
- ◆ Working-age population that is unemployed (not working, whether looking for work or not—the official definition of unemployment in South Africa).
- ◆ People living in a traditional dwelling, informal shack, or tent.
- ◆ Households with no piped water in their house or on site.
- ◆ Households with a pit or bucket toilet or no form of toilet.
- ◆ Households which do not have access to electricity, gas, or solar power for lighting, heating, or cooking.

A technique called principal component analysis (PCA) was then used to produce a composite index of deprivation. The objective of the PCA was to create an index of composite measurements that reflects social and material deprivation from a set of variables that are indicators of deprivation. Using the DI, the 52 districts in South Africa were then ranked into socioeconomic quintiles. Those districts that fell into the lowest quintile (the bottom 20 per cent) were the most deprived districts.

In the final part of the analysis various health problems and indicators could be correlated with the DI to provide an understanding of the impact that deprivation contributes to health inequalities. The result is displayed in a bar chart showing the districts ranked by district and grouped by quintile with unique colours for each of the nine provinces in which the districts fall. This provides a simple graphic way of illustrating the districts needing intervention.

National health insurance and universal coverage

The terms national health insurance (NHI) and universal coverage (UC) have been used interchangeably, to indicate the two essential components of an equitable health system, universal access to services at health facilities and elimination of financial barriers to care. For example, the World Health Report 2011, endorsed by the World Health Assembly, urged member states to 'aim for affordable universal coverage and access for all citizens on the basis of equity and solidarity' (World Health Assembly 2011). Several countries have lately developed policy proposals to pursue this goal. NHI and UC are rooted in a human rights philosophy: the right to health and the right to social security, which could, at a stretch, be extended to the rights to life and freedom. These policy tools aim at achieving social justice through establishing equity in health. These systems, common and effective in richer countries, have been introduced recently in countries at different levels of development: Brazil, Thailand, China, Mexico, Ghana, and

Tanzania. Before we describe a few of the most striking examples, we dwell on the substantial difficulties in the early stages of implementation, and use South Africa, the most extreme example of inequity, as a case in point

South Africa—the legacy of colonialism and systematic oppression

South Africa, with its population of about 51 million people, has a nominal gross domestic product (GDP) per capita of US \$8066 and Human Development Index (HDI) of 0.619³ and is a middle-income country. Despite almost a century-long positive engagement with the idea of a NHI and more recently a willing political leadership with a receptive population, the country illustrates the numerous hurdles to achieving UC to healthcare. South Africa, although the largest economy in Africa, has a high rate of poverty and low GDP per capita with an unemployment rate of about 25 per cent and among the top ten countries globally for income inequality as measured by the Gini coefficient. The Lancet South Africa Series in 2009 (Abdool Karim et al. 2009; Chopra et al. 2009; Coovadia et al. 2009; Mayosi et al. 2009; Seedat et al. 2009) showed clearly the residual imprint of the colonial and apartheid eras, an inequitable and inefficient health system, feeling the weight of multiple health burdens, and a backdrop of pervasive racial disparities in socioeconomic indicators, with high levels of poverty and unemployment, despite progressive policies.

The solutions proposed in the Series dealt primarily with recommendations on health systems strengthening. It was believed that these actions could be implemented from 2009 when a new administration took office, by an established and more capable Health Ministry working with functioning provincial counterparts, and a receptive population willing to participate in public health programmes.

Leadership has indeed been a critical element of change in South Africa's recent history. Within the health management bureaucracy there has been stasis for more than 10 years (Abdool Karim et al. 2009). Weakness in the supervision and leadership of the public sector has resulted in falling performance of public servants which is a major factor in poor government delivery of health, educational, and other services. The public sector faced a shortage of staff and specialized skills, and corruption undermined state legitimacy and service delivery. Leadership flaws cause tensions in the political-administrative interface in the public service with an erosion of accountability and authority, a lack of effective organizational design, inappropriate staffing, and low staff morale (Coovadia et al. 2009).

At the highest levels, the Health Minister and his senior staff have made radical policy changes and vigorously engaged leadership and civil society. The role of managers has been identified as crucial for transformation. Some of the other major forces envisaged likely to influence change in the health system were relative stability, growth of the economy, intersectoral engagement (government, civil society, business, funders and global initiatives), high-quality research, and a clear programme of action.

The outcomes from these programmes may be realized if the policy proposals by the government of South Africa, especially on 'universal coverage' (Republic of South Africa 2011; Mills et al. 2012), are successfully implemented. Recent policies envisage that the NHI will be phased in over a period of 14 years and it will gradually transform the existing health system distorted currently by

both race and class into a new NHI providing universal coverage based on principles such as social cohesion, equity, social solidarity, fairness, affordability, appropriateness, and effectiveness.

Recent progress on the NHI following release of a Green Paper described later in this section has been regularly reported in the media (South Africa Council for Medical Schemes 2009; KPMG 2011; National Planning Commission 2011). Over 75 per cent of all public health facilities have been audited, but few facilities yet comply with standards and norms.

The new policy aims, in particular, to overcome the inequities and inefficiencies of the current two-tier system between a well-resourced private sector and poorly resourced public sector (Shisana 2010). The inequities are worsening; over the past decade, private hospital costs and specialist costs have increased above the Consumer Price Index (South Africa Council for Medical Schemes 2009), and there is further maldistribution of specific skilled human resources to the advantage of the private sector. The arguments in favour of an NHI, and comparisons with other countries, have been provided in the 'Green paper' (Republic of South Africa 2011) and shown in recent studies (South Africa Council for Medical Schemes 2009; Mills et al. 2012).

A 're-engineered PHC' will realign the dominance of a curative and hospital-centred service. Quality control and regulation will be implemented through the Office of Health Standards Compliance. The NHI will be funded from a number of sources: a mandatory tax, the fiscus, and from a payroll tax (South Africa Minister of Finance 2012); 'sin taxes' have also been raised unofficially in public discussions by state officials. A fundamental criticism is that there is very little chance of successful implementation of the NHI in the present situation of a debilitated, inefficient, ineffective, and dysfunctional state.

We have shown that it is not simply a lack of funds or even facilities which are the central factors to explain the poor health and development returns under the current system (Coovadia et al. 2009). There is, as pointed out earlier, a national unevenness in the capabilities of the civil service (Chopra et al. 2009). A recent publication comes to similar conclusions on the central problem of implementation and capability of the state (National Planning Commission 2011). The costing of the NHI has been both supported (Shisana 2010) and criticized by local economists (van den Heever n.d.). The 2012 Budget anticipates that the real GDP growth will stabilize to 4.2 per cent per annum by 2014 (South Africa Minister of Finance 2012). KPMG's recent report is much more optimistic and indicates the benefits of externalities (KPMG 2011). It is evident that much more operational and implementation research will be required given the complexity and scale of the transformation necessary to establish the NHI.

In a recent comparison of financing of health services in Ghana and Tanzania in comparison to South Africa (Republic of South Africa, 2011):

overall health-care financing was progressive in all three countries, as were direct taxes. Indirect taxes were regressive in South Africa but progressive in Ghana and Tanzania. Out-of-pocket payments were regressive in all three countries. Health-insurance contributions by those outside the formal sector were regressive in both Ghana and Tanzania. The overall distribution of service benefits in all three countries favoured richer people, although the burden of illness was greater for lower-income groups. Access to needed, appropriate services was the biggest challenge to universal coverage in all three countries.

Syria—the subtle impacts of neo-liberalism

Syria has a population of 20.8 million people and a nominal GDP per capita of US \$2802 and HDI of 0.632. For many years, joblessness, food riots, and hunger have become commonplace, and like many lower- and middle-income countries much of this being related to structural reforms and austerity measures promoted in the past by the International Monetary Fund and World Bank.

More recently, the volatility and uprisings of several countries in the Arab world, typified by Syria, have often been oversimplified as simply being viewed as an expression of the popular clamour for democracy. What is often less understood is that the situation is a manifestation of underlying economic dysfunction which has been fuelled, *inter alia*, by misplaced development efforts of Western countries keen to promote market reforms. Kasturi Sen and Waleed al Faisal (Sen and Faisal 2012) investigated the neo-liberal economic policies implemented in Syria and showed that it is leading to rising health inequity in the country. Although health indicators have been improving in Syria over the last 30 years, infant mortality rate (132 in 1970 to 14 in 2010); under-5 mortality (164 in 1970 to 16 in 2010); and maternal mortality rate (482 per 100,000 registered live births in 1970 to 45 in 2010), the introduction of neo-liberal market reform policies from 2003, several years before the current volatility, have begun to reverse these gains. Supported by the European Union and German Technical Cooperation agency, the Syrian State included in its 10th Five-Year Plan (2006–2010) a package of economic liberalization policies. Changes made to the operation of the health sector and the labour environment included: new health insurance schemes to replace universal coverage, fee-for-service charges introduced at public hospitals, which also led to numerous job losses. The impact was felt mainly at primary healthcare level where the increases of user fees have increased out-of-pocket expenses with the net result that the people can no longer afford the service, and rising disparity and inequity.

There is now evidence (Sen and Faisal 2012) that the economic liberalization measures are playing a significant role in reversing the gains previously made, reinforcing the rich–poor divide, fostering inequality, suffering, social divisions, and creating discontent, consequences which have often been overlooked by Western observers. In Syria, previously providing a top-down centrally managed state with a command and control structure and a strong emphasis on public health, primary care, health promotion, and disease prevention which, while being directive, had led to important health gains. The new measures, however, introduced to liberalize and commercialize the health system, despite benevolent intentions, have produced the opposite effect. While the West views discontent in Syria as largely political, the fact that it had been behind the promotion of liberalizing economic reforms is either discounted or dismissed (Sen and Faisal 2012).

Thailand—transforming towards universal access to health

Thailand has a population of 70 million, a nominal GDP per capita of US \$5394 and HDI of 0.682. After improving health infrastructure for 30 years and implementing a range of different financial risk protection schemes over 40 years, Thailand was finally able to achieve universal health coverage in 2002 (Evans et al. 2012). This provides health insurance for all Thai citizens which guaranteed them access to a comprehensive package of health services.

Although this achievement was the result of many factors, the most significant intervention was an inspiring health reform scheme known as the Universal Coverage Scheme (UCS).

The intervention included policy formulation and implementation to provide an equitable entitlement to healthcare for all Thais in the form of a universal coverage system with three main features: (1) a tax-financed scheme providing services at the point of delivery free of charge. Although a small co-payment or fee of 30 baht or US\$ 0.70 was charged per visit or admission, this was later abandoned in 2006. (2) A comprehensive benefits package with a primary care focus, including disease prevention and health promotion. (3) A fixed budget with caps on provider payments to control costs. In addition to this several mechanisms were set up to protect UCS beneficiaries. This included more stringent hospital accreditation requirements, an information hotline, a patient complaints service, and a no-fault compensation fund.

By the end of 2001 the UCS provided coverage to 75 per cent (47 million) of the Thai population. This was an especially impressive achievement given that 18 million people had previously been uninsured. Furthermore the 25 per cent of the population (18 million people) not covered in the UCS were either civil servants, retired people and dependants, covered by the Civil Servant Medical Benefit Scheme (CSBMS), or participants of the contributory Social Security Scheme (SSS) which covered private-sector employees.

Achieving the establishment of the UCS was remarkable. Not only was it achieved in the aftermath of the 1997 Asian financial crisis when the per capita gross national income was very modest (US \$1900), but it went against the advice of external experts sceptical of its financial viability and was implemented with unprecedented speed.

In a recent 2011 assessment, which, a decade after its implementation, aimed to review the scheme's performance, the results show the impressive extent to which health inequities have been addressed, teasing out also what worked well and what did not; the reasons for these outcomes in equity were also elucidated (Evans et al. 2012). It was found that between 2003 and 2010 the number of outpatient visits rose from 2.45 to 3.22 per member per year and the number of hospital admissions rose from 0.094 to 0.116 per member per year. This improved access has led to much greater service equity and reduced medical impoverishment, which are indicators of the additional number of non-poor households falling below the national poverty line caused by the out-of-pocket costs of medicines and/or health services. This decreased significantly from 2.71 per cent in 2000 before the UCS was introduced to 0.49 per cent in 2009. It is not surprising that there is now a very low level of unmet need for health services in Thailand.

The UCS has led to a situation where there has been a marked decrease of out-of-pocket expenditure, which has been compensated for by an increase of government health sector spending through public subsidy. This progressive pro-poor spending has eliminated the rich–poor gap in out-of-pocket expenditure.

In addition to the described outcomes the scheme's success has proved to be resoundingly popular. The high percentage of UCS members who express satisfaction has grown from 83 per cent in 2003 to 90 per cent in 2010. Encouragingly also for the private sector, was that although many contracted healthcare providers were initially unhappy with the UCS, their own satisfaction rose from 39 per cent in 2004 to 79 per cent in 2010.

Although there has been much impressive improvement as already described, some other important areas that were part of the ambitious UCS reform did not make the same gains. There was very little strengthening of the primary healthcare system, primary prevention was not effective, and the reliability of the referral system is still weak. Furthermore there has not been much progress towards rationalizing the three insurance schemes; this revealed that further challenges were related to the political influences and power dynamics of institutional reform.

It is important to note that politicians, civil society, and technocrats all played major roles in pushing for the UCS reform. It required securing parliament's commitment to universal health coverage and advocacy through the policy, design, implementation, and evaluation processes. Prior experience gained from existing health insurance schemes was both positive and negative, and the lessons learned proved helpful in designing the UCS. The rapidity with which the plan was rolled out was because, even in 2001, Thailand already had a firm foundation upon which to implement the scheme. There was an extensive network of government-owned district health facilities, well-established health policy and systems, research institutions, public health administration capacities, and a computerized civil registration system.

One of the important innovations in the creation of the UCS was the creation of the National Health Security Office (NHSO) which acted as the purchaser on behalf of UCS beneficiaries. This meant that the Ministry of Public Health (MOPH) no longer wielded control over government spending on healthcare services and was able to focus on improving the quality of service provision. Throughout the process, research was vital in building up a supportive body of evidence. This was essential in countering fierce resistance to change from some stakeholder groups and establishing a critical mass of support.

There are important lessons in establishing universal coverage including extension of access to services, containment of costs, and strategic purchasing. Financing reform must go hand in hand with improving physical access to services.

India—shifting towards NHI at scale

India, the second largest country by population (with over 1.2 billion people), is the most populous democracy in the world. It has a nominal GDP per capita US \$1388 and HDI of 0.547. Despite enormous recent development strides, the Indian economy is still, however, only the world's tenth-largest by nominal GDP. From 1991 the country began to adopt market-based economic reforms and has since become one of the fastest-growing major global economies, even though it is still a newly industrializing country. India faces many challenges. These include poverty, illiteracy, malnutrition, poor healthcare, and corruption. Indeed, though planning for a UC has begun, there remain deep flaws in the Indian Health System (High Level Expert Group 2011). *The Lancet* ran a series of seven papers on India with the final article (Reddy et al. 2011) concluding on one of the points of major relevance to this paper: the creation of an integrated national health system through universal health insurance. It is recognized that for this to work it will have to offer good quality healthcare provided by well-trained health staff. Given the current organization of healthcare this will mean restructuring of health governance. It will also be necessary to develop greater engagement with the community and being proactive in developing the necessary legislation that would enshrine the important

health entitlements that the Indian people need and deserve. The current public health system which is the primary provider of promotive, preventive, and curative health services to most of the people in India, has to be greatly improved, and the other providers in the health system (including the private sector) need to be steered towards integration. A call is made in *The Lancet* series for India to achieve universal healthcare for all by 2020. Given the massive scale and need for reorganization, this call appears to be unrealistic. Sengupta and Prasada (2011) point out that the economic growth path of India is dominated by a powerful corporate private sector, whose actions exacerbate rather than ameliorate inequities. Hence the de facto planning process does not concern itself with the health burdens of the majority nor indeed deal with the persistent, widespread, and crippling poverty, and the need for a public sector response, but tends rather to drift towards a laissez-faire, free-market approach. Although India desperately needs an efficiently managed and well-resourced public health system based on the principles of UC, the markedly dysfunctional health system requires a paradigm shift in making the transition.

Mexico—a labour-based approach

Mexico, with a population of 115 million people (13th largest in the world), a nominal GDP of US \$10,153 per capita, and an HDI of 0.770, has a tragic history of colonization, dictatorship, rebellion, civil conflict, territorial wars, and economic instability. Against this background and despite great challenges, there has been surprising progress in implementing a UC scheme based on the principle of broadening coverage of workers (Knaul et al. 2012). In 2003, the country introduced *Seguro Popular*, an NHI scheme, which by 2012 had virtually become a UC which provided healthcare access to more than 50 million Mexicans previously excluded from insurance. The programme is based on three principles of protection: insurance against health risks, providing quality healthcare assurance, and insurance against the financial consequences of disease and injury. *Seguro Popular* has been successful in improving access to health services, providing financial protection, and reducing the prevalence of catastrophic health expenditures, which further impoverish the poor. *Seguro Popular* provides access to a package of universally comprehensive health services, which in Mexico is synonymous with social protection of health. Initially the system was a labour-based social security system but has progressed from then to become a vehicle for the universal social protection of health. The ethical basis for the reform is that access to effective healthcare is seen as a universal right based on citizenship. Each year the effects and impacts of the reform initiative are published and made available in the public domain through the scientific literature and release of new data. Despite the progress, the struggle to shift the health system so that it becomes an increasingly effective, equitable, and responsive health service remains a challenge. Further reforms will be required before the health system has been reorganized to function correctly. Nevertheless this carefully recorded documentation of the process to establish UC has considerable relevance for low- and middle-income countries.

Brazil—promoting equity through health and human rights

Brazil, the largest country in South America and the world's 5th largest country, both by geographical area and by population with

over 193 million people (with a nominal GDP per capita of US \$12,788 and HDI of 0.718), provides a striking example of how a country steeped in a long tradition of inequity can rapidly transform. It also shows that this can be achieved in a manner that is compatible with economic growth. Indeed with an impressive economic growth rate of 7.5 per cent (2010) Brazil has made formidable health achievements in recent years in fulfilment of the goal of universal, equitable, and sustainable healthcare and the right to health enshrined in its 1988 constitution (Kleinert and Horton 2011).

The historical development of the current health system has several unique features. Public health, created at the end of the nineteenth century has always featured as an important aspect of the health system. For example, two of Brazil's greatest scientific leaders, Oswaldo Cruz and Carlos Chagas, acted decisively against public health threats of the time. These included tropical diseases such as yellow fever, bubonic plague, and smallpox. In the process these public health interventions laid the foundation for the internationally renowned Oswaldo Cruz Foundation (FIOCRUZ) which continues these efforts and now employs over 7500 people across the country. It remains an institution which specializes in education, research, pharmaceutical, and vaccine production. Regrettably the health system was not always so progressive. Until 1985 a hospicentric, biomedical approach backed by a military dictatorship dominated the approach. Although it suppressed moves towards social and health equity, it nevertheless created the conditions for a strong civil-society movement that still flourishes today. With a change in government, that movement mounted a powerful drive for health reform, that ultimately resulted in the Unified Health System (SUS). These reforms broadened the definition of health beyond the biomedical paradigm. They incorporated stewardship into the thinking of the social determinants of health, education, poverty reduction, and preventive measures within the broader context of health as a human right. Especially interesting was the promotion of community participation at all administrative levels.

In 1989, Brazil was one of the most unequal countries. In the two decades since then, much progress has been made, which has significantly reduced regional and socioeconomic inequalities and poverty. According to the World Bank, poverty (at purchasing power parity of US \$2 per day) has fallen from 20 per cent of the 190 million citizens in 2004 to 7 per cent in 2009. In the health sector the SUS has vastly improved access to primary and emergency care, notably enabling Brazil to have already achieved one target of MDG 1, to reduce by half the number of underweight children. Brazil is also on track to meet MDG 4 and realize a reduction in the mortality rate of children younger than 5 years by two-thirds. Brazil's HIV/AIDS policies and achievements have also been widely praised.

Comparisons

There are different approaches to the incorporation of private healthcare into national systems of UC. There are seven countries which finance more than 20 per cent of their healthcare through private health insurance: Brazil, Chile, Namibia, South Africa, the United States, Uruguay, and Zimbabwe. In South Africa, where privatized health services comprise the largest financial proportion of the total health system, there are many barriers.

The dominance of the private sector places constraints on achieving a fair, just, and equitable health system (Sekhri and Savedoff 2005).

A recent study (Lagomarsino et al. 2012) examined the structure of NHI reforms in nine countries: Ghana, Indonesia, the Philippines, Rwanda, and Vietnam are five countries which are at intermediate stages of reform. Four (India, Kenya, Mali, and Nigeria) are at a very early stage. On the whole, progress is unsatisfactory. Although the authors report some progress towards UC, citing increasing enrolment in government health insurance, enlarging the benefits packages, and reducing out-of-pocket spending with an increasing of the share of government in health spending, it is suggested that it would be helpful if there was one set of common, comparable indicators of progress towards UC.

Important as UC is as a strategy, some key observers (Gwatkin and Ergo 2011; Latkoet al. 2011) have warned about over-optimism in the provision of UC through NHI.

Intersectoral action for health

Given the wide range of social determinants of health, it is clear that interventions are required in many sectors of society, hence the importance of intersectoral action.

In a systematic review of intersectoral actions to promote the socioeconomic determinants of health it was found that few studies have been able to assess their extremely complex and context-specific nature. In one such study, an expedited, systematic 3-month review critically appraised some 10,000 selected articles against review criteria and found only 17 which met the inclusion criteria (Ndumbe-Eyoh and Moffatt 2012): a few of these studies reported on interventions which deal with structural determinants of health. The evaluation of the impact of intersectoral action was mixed, showing that it had either a moderate effect or no effect on the social determinants of health, and consequently a limited effect on health equity.

Overall these findings (Ndumbe-Eyoh and Moffatt 2012) suggest that much of the literature on the social determinants of health to advance health equity is mainly descriptive. There has been up until this time little emphasis on undertaking interventions. There has been even less concern with the types of measurements required to evaluate these. The earlier cited study emphasized the lack of available high-quality, rigorously evaluated evidence.

Global initiatives to address health inequality

A book produced by the WHO (Blas and Kurup 2010), *Equity, Social Determinants and Public Health Programmes* and edited by Erik Blas and Anand Sivasankara Kurup, stemming from the recommendations of the CSDH, offers a collection of different approaches and analyses of the social determinants of health that impact on specific health conditions.

There has been a number of recent global initiatives aimed at reducing health inequities. One notable example of this is that at the conclusion of the 13th World Congress on Public Health, held 22–27 April 2012 in Addis Ababa (Ethiopia), the World Federation of Public Health Associations (WFPHA) produced the *Addis Ababa Declaration on Global Health Equity* (World Congress on Public Health 2012), which was 'a call to act on closing some of

the critical gaps in global health and well-being'. An article about the 13th World Congress on Public Health and the Addis Ababa Declaration by Dr Peter Byass, a Professor and Director of the Umea Centre for Global Health Research (Sweden), also appeared in the *Huffington Post* (Byass 2012).

A second example is the Global Health Corps. Founded in 2009, Global Health Corps (GHC) is developing a health equity movement by energizing a global community of emerging leaders. The programme had grown to 68 fellows, by 2012, serving in Burundi, Malawi, Rwanda, Uganda, and the United States (Global Health Corps 2012).

A third example is the Training for Health Equity Network (THEnet) (THEnet n.d.). THEnet is a consortium of health professional education institutions committed to achieving health equity. Responding to the priority needs of communities, it works by reforming medical education, research, and service. THEnet schools are consistent with this vision, demonstrating their social accountability by committing themselves to measure their own success by how well they meet the needs of people they serve.

A final example, the Global Action for Health Equity Network (Global Action for Health Equity Network n.d.) (HealthGAEN), is a global movement for health equity. It develops a programme of action to deal with the social and environmental determinants of health. It was established to build on the momentum, expertise, and partnerships that arose following the establishment of the WHO CSDH.

Global endorsement towards a new great transition

At the 67th meeting of the UN's General Assembly on 12 December 2012, the assembly unanimously adopted a resolution on global health and foreign policy. It urged governments to begin to move towards providing universal access to affordable and quality healthcare services (UN General Assembly 2012).

The Assembly also recognized that improving social protection was a necessary step towards UC. It saw social protection as empowering investment in people. It could assist people to adjust to changes in the labour market and economy. This was a necessary step to support a transition to a more inclusive, sustainable, and equitable economy. While planning or pursuing the development of UC, Member States were encouraged to continue investing in health-delivery systems. This was to be done to increase and safeguard the range and quality of services. It could also help meet population health needs.

Member States were also encouraged to recognize the interrelationships between the promotion of UC and other international policy issues, such as the social dimension of globalization, which includes inclusive policies, equitable growth, and sustainable development.

These global reforms, like those of demography and sanitation movements of the eighteenth and nineteenth centuries, and the continuing public health improvements in the twentieth century, including the expansion of immunization, promise another great transition—the provision of universal care by altering how the mechanisms of healthcare are financed and how health systems are organized (Forum on Universal Health Coverage 2012; Prince Mahidol Award Conference 2012; World Health Assembly 2011).

Notes

1. For more information about the WHO Commission on Social Determinants of Health, visit http://www.who.int/social_determinants/en.
2. Gini coefficient: this index measures the degree of inequality in the distribution of family income in a country. The index is calculated from the Lorenz curve, in which cumulative family income is plotted against the number of families arranged from the poorest to the richest. If income were distributed with perfect equality, the Lorenz curve would coincide with the 45-degree line and the Gini index would be zero; if income were distributed with perfect inequality, the Lorenz curve would coincide with the horizontal axis and the right vertical axis and the index would be 100 (Central Intelligence Agency 2012; World Bank 2012).
3. The Human Development Index (HDI) is a composite statistic of life expectancy, education, and income indices to rank countries into four tiers of human development. It was created by economist Mahbub ul Haq, followed by economist Amartya Sen in 1990, and published by the United Nations Development Programme. Its range is between 0 and 1 with higher indices being more desirable.

Genomics and public health

Vural Özdemir, Wylie Burke, Muin J. Khoury,
Bartha M. Knoppers, and Ron Zimmern

Introduction and historical perspectives of genomics and public health

A grand challenge for twenty-first-century medicine is to understand how knowledge about human genomic variation and its interaction with the environment can be used, across the lifespan, to improve health and prevent disease. Some genomic applications are already well embedded in health systems; for example, many countries have newborn screening programmes that aim to reduce morbidity, mortality, and disability in people affected by hereditary conditions. The scope and context of genomic applications have evolved, however, since the completion of the Human Genome Project a decade ago. A growing number of candidate applications are currently in transition from basic science to public health practice, in the face of an increasingly global science (Rajan 2006; Bernstein et al. 2011; Hotez 2011; Lancet editors 2011; Suresh 2011; Dandara et al. 2012). Between 2009 and November 2012, more than 450 new genomic tests were identified from horizon scanning by the US Centers for Disease Control and Prevention (GAPP Finder 2012).

Until recently, genomics and public health rarely came together except in the context of population screening programmes for certain rare single-gene disorders (Burke et al. 2010; Zimmern 2011; Zimmern and Khoury 2012; Ozdemir 2014). The first of these was newborn screening for the inherited metabolic disease phenylketonuria (PKU), for which biochemical screening and diagnostic tests became available during the 1960s (Botkin 2005). Although this genetic disease was rare, screening was recognized as a public health responsibility because early diagnosis and treatment of affected infants could prevent serious mental and physical disability in the population.

As new interventions such as antenatal diagnosis for genetic disorders were developed during the next few decades, geneticists and some public health professionals became involved in assessing population needs for services offering these interventions (Royal College of Physicians of London 1991) and, in countries such as the United Kingdom where public health has a role in healthcare service organization and delivery, in commissioning and allocating resources for them. Enthusiasm for population screening broadened after the success of the early newborn screening programmes, to include screening adult populations for certain genetic conditions. However, a general distrust of public health motives for population screening, together with the malign legacy

of the eugenics movement of the early to mid twentieth century, resulted during the late 1970s and 1980s in the distancing of medical genetics from mainstream public health.

The impact of the Human Genome Project: from medical genetics to genomic medicine

In 1990, the Human Genome Project began. This ambitious enterprise aimed to sequence the entire 3 billion DNA base pairs of the human genome within a 15-year time frame, providing the raw material for discovering the sequences of the complete set of human genes and, eventually, discerning their functions and how they contribute both to normal physiology and initiation and progression of disease. As it turned out, the sequencing project was finished ahead of schedule: a ‘reference sequence’ for the genome, including the almost complete sequences for its complement of around 25,000 genes, was published in 2003 (Collins et al. 2003).

The Human Genome Project accelerated progress in finding the genes that, when mutated, cause heritable diseases such as cystic fibrosis, Duchenne muscular dystrophy, and Huntington’s disease. By the early years of the twenty-first century, the genes implicated in some 1800 of these genetic diseases (most of them very rare) had been identified and catalogued in the Online Mendelian Inheritance in Man database (Online Mendelian Inheritance in Man, OMIM® n.d.). The availability of molecular diagnosis for many of these conditions began to transform the practice of medical genetics and spurred attempts to find effective treatments.

The Human Genome Project also generated data and tools for a new wave of genetic epidemiology projects to search for gene-disease associations. In an effort to provide tools for such studies, research consortia, largely funded by public funding sources, instigated first the single nucleotide polymorphism (SNP) project and then the HapMap, 1000 Genome Project, the Encyclopedia of DNA Elements (ENCODE), and the Human Variome Project (Guttmacher and Collins 2005; ENCODE Project Consortium 2012; Patrinos et al. 2012). These initiatives collectively provided a map of common structural and functional variation across the genome in different populations. These resources are beginning to bear fruit in whole-genome association studies, where markers distributed across the entire genome are scanned for putative associations with the environment, a disease, or other phenotypes such as drug effectiveness and safety (Nuzhdin et al. 2012; Ritchie 2012). These studies, often carried out by large international consortia and involving many thousands of study participants, have also signalled the rise of ‘infrastructure science’ such

as population biobanks, consortia and networks, and cloud computing that coexists with, and sustains, the classic discovery science (Knoppers and Hudson 2011; Shanker 2012; Knoppers and Özdemir 2014). The introduction of genomic infrastructure science has successfully led to discovery of common genomic variants associated with conditions including type 2 diabetes, coronary artery disease, and breast cancer (see, for example, The Wellcome Trust Case Control Consortium 2007; Nuzhdin et al. 2012).

During the same period, attention has also turned towards the subject of ‘normal’ human genetic variation and the opportunity of using data-intensive ‘omics’ technology platforms (genomics, proteomics, metabolomics) developed as a result of the Human Genome Project to identify biomarkers for common human diseases. A biomarker, as noted by the US National Institutes of Health (NIH) Biomarkers Definitions Working Group, is ‘a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention’ (Biomarkers Definitions Working Group 2001). Seen in this light, a biomarker can be genetic, biochemical, or any other clinical measure, provided that it meets the definition as an indicator (Collins and McKusick 2001; Gutmacher et al. 2001; Burke and Trinidad, 2011; Khoury et al. 2012a; Özdemir et al. 2012).

Public health genomics

The population-level goals of the Human Genome Project, and the expectation that it will have a major impact on clinical health services and disease prevention, make the evaluation of genomics as a component of public health practice an essential part of the current life sciences agenda (Burke et al. 2010; Khoury et al. 2012a, 2012b). Genomics may assist public health practitioners to address heterogeneity of risks and stratified interventions. Genomic factors may also contribute to the assessment and management of important public health issues such as environmental health, nutrition, vaccines and infectious disease (Zimmern 2011). The growing understanding of genomic contributors to disease need not detract from efforts to address disease modifiable risk factors such as environmental exposures, social structure, and lifestyle. Rather, the unproductive debate about nature versus nurture can now be replaced with an integrated and synergistic approach of nature *and* nurture in public health practice (Burke et al. 2010; Zimmern 2011; Zimmern and Khoury 2012).

As with other emerging technologies, the challenge is to devise an efficient strategy to strike the right balance between ‘premature translation’ of genomics discoveries to public health practice versus the ‘lost in translation syndrome’ where genuine innovations fail to be recognized or used in practice, be it in clinical medicine or public health. A related challenge is to weigh the potential benefits and harms of genomics applications. The recognition of these challenges and opportunities and the need for an overarching integrative strategy to address them have led over the last decade to the emergence of the new field of public health genomics (Khoury 2003; Khoury et al. 2000, 2012a; Stewart et al. 2007).

This chapter outlines the theoretical underpinnings of public health genomics and its applications in practice. We then look in detail at important areas where public health and genomics intersect, underscoring populations as heterogeneous and dynamic

structures: the use and evaluation of genetic and genomic tests, the criteria for population screening programmes involving genomic factors, and the use of genomics in disease prevention. We provide a three-tiered approach to group public health genomics applications based on their readiness for practice (Khoury et al. 2011). This is essential because we now have reached a stage in the field where claims for genomics tests are rapidly proliferating well beyond newborn screening. An evidence-based approach to public health genomics practice equips researchers, practitioners, patients, and policy makers with tools for informed decision-making. We note that new and innovative ways to evaluate evidence on new genomics applications are needed (Evans and Khoury 2013). Indeed, we will likely never have sufficient resources or time to conduct randomized controlled trials for each candidate genomics test. Of particular concern is the ascertainment of clinical and real-life utility of new genomics tests that will vary in different contexts. These analyses are followed by horizon-scanning on ‘big data’-driven public health science, using the intersection of vaccine science and genomics (vaccinomics) as an example. We conclude by a consideration of the ethical principles for the application of genomics in public health practice and the challenges and prospects for public health genomics.

We assume that readers have an understanding of the basic principles of genetics. A glossary of important terms and their definitions is provided in Box 2.5.1.

Genes as determinants of health

The new era of genomics recognizes genes as one of the determinants of health (Fig. 2.5.1). An important feature of this model is that it emphasizes the interplay between genomic and environmental factors (an ‘environmental’ factor in this context is anything that is not genomic).

DNA sequence variation is not the only source of variation in gene function. In multicellular organisms, different types of cells acquire their functional characteristics by expressing different subsets of their genome in a specific temporal pattern. Differential gene expression is associated with chemical modifications to the DNA (such as methylation) that do not change the primary DNA sequence and are termed epigenetic. As cells of a specific type multiply, they stably transmit these epigenetic modifications to the cells they give rise to. Epigenetic mechanisms are likely to play a role in mediating changes in gene expression in response to environmental signals (Slomko et al. 2012). Epigenetic mechanisms are emerging as an important consideration in many common complex diseases, including diabetes and cancer (Sandoval et al. 2012; Slomko et al. 2012). Epigenetic changes are not generally thought to be heritable by the organism’s offspring but there is evidence that trans-generational effects may occur (Richards 2006; Bohacek et al. 2012). More significantly, clarification of the role of epigenetics in disease aetiology may have important implications for public health action, related to the environmental factors associated with epigenetic change.

As discussed in Chapter 5.12 on genetic epidemiology, genetic components of human traits are dynamic, be they disease or drug exposure related, and fluctuate depending on the environmental context (Kalow et al. 1999; Özdemir et al. 2005; Begum et al. 2012). A book by Tobias et al. (2011) provides additional, practical background to all aspects of medical genetics and its clinical practice.

Box 2.5.1 Glossary of basic terms in genetics and genomics

Alleles	Variant forms of the same gene
Autosomes	Chromosomes that are not concerned with sex determination. Humans have 22 pairs of autosomes and two sex chromosomes
Biomarker	A factor used to indicate or measure a static or dynamic biological process (for example, a specific protein or genetic polymorphism)
Carrier	Usually refers to an individual who is heterozygous for a recessive disease-causing allele
Chromosomes	The structures within cells that carry the genetic information in the form of DNA
Dominant	A characteristic that is expressed even when the relevant gene is present in only one copy
Epigenetic	A factor or mechanism that changes the expression of a gene without affecting its DNA sequence, and is stably transmitted during cell division
Genome	The complete set of genetic information of an organism
Genotype	The specific genetic constitution of an individual
Germline	Relating to the sex cells, which transmit genetic information from one generation to the next
Haplotype	A specific set of alleles located on the same chromosome
Heterozygous	Carrying two different alleles of a gene
Homozygous	Carrying two identical alleles of a gene
Karyotype	A description of the number and structure of chromosomes in an individual
Locus	The location of a gene or DNA marker on a chromosome
Marker	A gene or other segment of DNA whose chromosomal position is known
Meiosis	The specialized cell division that takes place when sex cells (sperm or eggs) are produced. The members of each chromosome pair separate so each sex cell receives only one copy of each gene
Mendelian	Relating to the laws of inheritance discovered by Gregor Mendel
Mutation	A change in the sequence of DNA
Nucleotide	The molecular units that make up DNA and RNA. A nucleotide of DNA consists of a base (A, C, G, or T) linked to the sugar deoxyribose and a phosphate group
Penetrance	The likelihood that an individual carrying a specific genetic variant will show the characteristic determined by that variant
Phenotype	The observable traits of an organism such as eye colour and disease characteristics or response to a health intervention (e.g. drug side effects)
Polymorphism	A common genetic variant or allele (present in at least 1 per cent of the population)
Recessive	A characteristic that is only expressed when two copies of the relevant gene are present
SNP	Single nucleotide polymorphism: a DNA sequence variation that involves a change in a single nucleotide
Somatic	Relating to the cells of the body other than the germline (sex) cells and their precursors

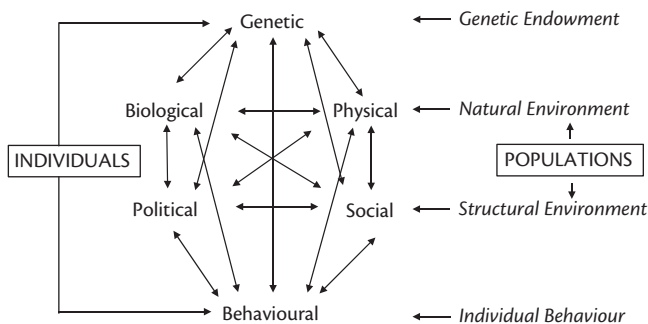

Fig. 2.5.1 Determinants of health.

Genomics and improving health

In this section, we discuss the range of use of genetic and genomic tests for improving population health. Some uses, such as newborn screening programmes, represent public health interventions. Others represent the use of genetic tests and knowledge in clinical care.

Newborn screening

Most highly penetrant genetic diseases are incurable, but clinical management of many of these conditions has improved in recent years, and for some conditions, life expectancy has increased significantly. In some cases, early detection of the disease, and early initiation of treatment, can significantly reduce mortality and

morbidity. The classic example is the disease PKU, which is caused by deficiency of the enzyme phenylalanine hydroxylase (Kaye et al. 2006). If the disease is untreated, build-up of phenylalanine causes irreversible brain damage soon after birth. Early detection and initiation of a phenylalanine-free diet enables near-normal development. Sickle cell disease and cystic fibrosis also respond to early diagnosis and initiation of treatment in the newborn period, though the benefits are less dramatic than for PKU (Kaye et al. 2006). Newborn screening programmes may have other less direct benefits, such as in sparing parents of an affected child the often prolonged process of obtaining a diagnosis, and in counselling parents about the risk to subsequent pregnancies.

Newborn screening programmes for various conditions are in place in many Western countries. In some jurisdictions, including the United States, newborn screening programmes are state-mandated. In others, for example the United Kingdom, parental consent is sought. The apparent success of newborn screening for PKU, the development of new diagnostic technologies such as tandem mass spectrometry, and powerful advocacy by patient groups have led to pressure for widening newborn-screening programmes to include an increasing number of conditions. The Secretary's Advisory Committee on Heritable Disorders in Newborns and Children recommends screening for 31 core disorders and 26 secondary disorders (US Secretary's Advisory Committee on Heritable Diseases of Newborns and Children 2011).

There is ongoing debate about the scope of newborn screening (see Chapter 11.4). Serious concerns have been expressed about pressures to expand newborn screening panels (Botkin et al. 2006; Grosse et al. 2006; Elliman 2012). A major criticism is that many of the additional conditions depart from the key criteria identified (Wilson and Jungner 1968) for ensuring that population screening programmes deliver public health benefits. These criteria include the need to demonstrate that the natural history of the disorder is understood, that the characteristics of the screening test have been thoroughly evaluated, that an effective preventive intervention is available, and that screening is necessary to prevent death or serious disability. Some have called for a clear distinction between screening tests that meet the original goals of newborn screening, focused on improved health outcomes for infants, while others have called for expanding the purpose of newborn screening, to include other benefits, such as providing information to parents about reproductive risk or creating opportunities for research on rare diseases (Bailey et al. 2005; Alexander and van Dyck 2006; Baily and Murray 2008; President's Council on Bioethics 2008; Cody 2009).

The approach to the assessment of potential population screening programmes varies in different countries. In the United Kingdom, a National Screening Committee considers the evidence base for all proposed screening programmes, including those for genetic conditions. The Health Technology Assessment research programme has carried out reviews of newborn screening for some conditions (see, for example, Pandor et al. 2004), and most proposed programmes are piloted on a regional basis before being rolled out nationally. For example, a national newborn screening programme for medium-chain acyl-CoA dehydrogenase deficiency (MCADD) was introduced following a successful pilot study (National Screening Committee 2007). Ideally, research and clinical trials of new screening technologies should

be funded promptly and adequately so that evidence to inform decisions about proposed screening programmes can be obtained as efficiently as possible.

Using genomics in risk assessment and disease prevention

An ultimate objective for those wishing to apply genomics in public health would be the ability to use genotypic information to identify groups of individuals who are at increased risk of disease and who could be offered opportunities to reduce their risk by means of interventions aimed at modifiable environmental factors such as diet. However, this is by no means a simple goal to attain.

The predictive value of genotypic information

The first problem in using genotypic information for prevention is the low penetrance of most of the alleles implicated in susceptibility to common disease. Individually, such alleles are typically associated with odds ratios of around 1.1 to 2.0, though rarer alleles may confer higher risks. For this reason, the positive and negative predictive values of tests for single alleles are likely to be low (see Fig. 2.5.2): most individuals who tested positive would gain no benefit from a preventive intervention because they would not have developed the disease in any case. Those who tested negative might be falsely reassured.

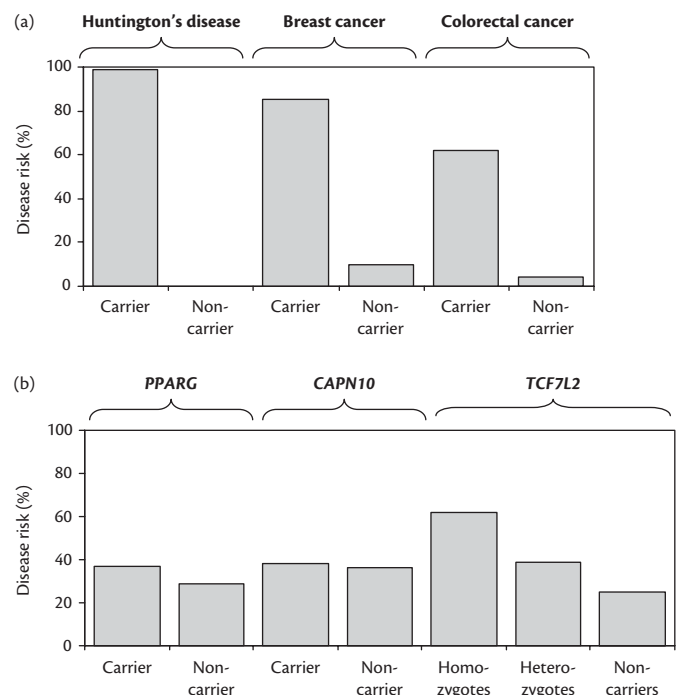

Fig. 2.5.2 Disease risks of carriers and non-carriers in genetic testing. In monogenic (Mendelian) disorders (a), carriers have a substantially increased risk of disease; non-carriers have a disease risk that approximates the population average. In the case of common disease (b), because risk alleles are generally common (population frequency 1 per cent or higher), carriers and non-carriers have disease risks that are only slightly higher or slightly lower, respectively, than the population average.

Reproduced with permission from Janssens and Khoury, Predictive value of testing for multiple genetic variants in multifactorial diseases: Implications for the discourse on ethical, legal and social issues, *Italian Journal of Public Health*, Year 4, Volume 3, Number 3–4, pp. 35–41, Copyright © 2006.

Some premature applications of genotypic information in prevention have been advocated. For example, since the discovery of the *HFE* gene, which is mutated in the iron-overload disease hereditary haemochromatosis, population screening for hereditary haemochromatosis has been proposed, based on *HFE* genotype. The rationale is that serious disease (liver cirrhosis, fibrosis, or diabetes) may be prevented by the simple procedure of frequent phlebotomy. However, although about 25–50 per cent of people with a predisposing *HFE* genotype have evidence of iron overload, it is not known how many of these people would, if untreated, progress to symptomatic disease; the penetrance of overt liver disease may be as low as 1–10 per cent. Public health has played an important role in the evidence-based evaluation of population screening for hereditary haemochromatosis.

It has been suggested that the predictive power of genotypic information would be increased if more alleles were considered together. This approach is called genomic profiling (Yang et al. 2003). Although individuals who carry multiple risk alleles will have a very high risk of disease, these individuals constitute a very small percentage of the population (Janssens et al. 2004). For the bulk of the population, genomic profiling will be extremely complex, depending on the number of risk genotypes tested for, the spectrum of risk alleles an individual carries, and the odds ratios associated with each of them (Janssens and Khoury 2006).

Pleiotropic effects of susceptibility genes must also be taken into account. For example, the *APOE4* variant increases risk for both Alzheimer's dementia and coronary heart disease but reduces risk for macular degeneration. Interventions aimed at preventing the negative effects of a gene variant might increase risk for another disease.

Behavioural responses to genomic risk information

The second problem is whether risk information based on genetic factors is likely to be effective in motivating the *sustained* behavioural change that would be needed to achieve health benefits. Current evidence on this issue is limited and more research is needed. The availability of an effective intervention is also important, as is the individual's assessment of his or her ability to achieve behavioural change; this assessment, in turn, is strongly dependent on the person's familial and social environment. There is some evidence that reactions to genetic risk information may differ from those to other types of risk information. For example, a recent study of individuals recently diagnosed with familial hypercholesterolemia through DNA testing found that perceived risk, and perceived efficacy of medication were higher than the 'no genetic predisposition' control sample (Claassen et al. 2012). This points to the need to present genetic risk information in such a way that it does not undermine the individual's belief in the efficacy of behavioural change.

There could also be a danger that information indicating an average or reduced genetic risk might be falsely reassuring, leading people to underestimate their risk and ignore advice about a healthy lifestyle. To date there is little evidence that false reassurance is a significant concern, though some more subtle effects of negative genetic test results have been observed. For example, among people with a family history of Alzheimer's disease (and therefore at increased risk),

those whose risk estimate included a negative test result for the *APOE4* polymorphism perceived their risk as lower than those with the same risk estimate based only on family history information (LaRusse et al. 2005).

A further relevant factor is the likelihood that people will take up an offer of genetic testing to indicate their risk. The public health impact of genetic susceptibility testing is likely to be low if few are motivated to take advantage of it. Those who have poor motivation to improve their health through behavioural and lifestyle change, or perceive a test result as a threat to their well-being rather than an opportunity to improve their health, are unlikely to perceive benefits from genetic susceptibility testing.

High-risk versus population approaches to prevention

The fundamental rationale for using genomics in the primary prevention of common diseases with environmental causes has also been questioned (see, for example, Merikangas and Risch 2003). One argument is based on Rose's (1985) observation that a greater reduction in overall disease incidence can be achieved by a small reduction in disease risk over a whole population, whereas targeting an intervention at a high-risk group results in a larger absolute reduction in risk for those individuals.

A further issue is the need for caution in applying population-derived risk estimates to decisions about individual patients (Rockhill et al. 2000). For example, Elmore and Fletcher (2006) have calculated that, although the Gail model for breast cancer risk prediction performs well at a population level, with a concordance of 0.96 between the expected and actual number of women in a population who develop breast cancer, at an individual level the concordance is only about 0.6. This problem is, of course, not unique to risk estimates based on genetics. Population-based risk estimates may best be used to stratify risk (so that, for example, an individual falls into a specific quintile) rather than to attempt to pinpoint individual risk. Population-based data will generate hypotheses about preventive action but these hypotheses must be tested rigorously in prospective outcome studies. Scientifically validated genotypic risk information is best used to enhance the predictive value of a 'package' of risk information that also incorporates measures of lifestyle and behavioural factors as well as relevant phenotypic biomarkers (Haga et al. 2003). Another approach is the Boadicea (Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm) that is used as a risk model to compute *BRCA1* and *BRCA2* mutation carrier probabilities and age-specific risks for breast and ovarian cancer (Antoniou et al. 2008). Further research is needed to determine the best way to communicate genetic risk information in order to achieve beneficial health outcomes.

Using family history in disease prevention

It is likely to be many years, perhaps decades, before it will be possible to use genotypic information routinely in the assessment of risk for common chronic diseases. It has been suggested that, in the meantime, family history information represents a useful surrogate that could be used more effectively and systematically in preventive healthcare than is currently the case (Yoon et al. 2002; Khoury et al. 2010b).

Family history is a risk factor for almost all diseases of public health significance, including most chronic diseases. Family

history reflects the consequences of shared genetic variation at multiple loci (first-degree relatives such as siblings share 50 per cent of their genes), shared exposures to environmental factors, and shared behaviours.

Methods have been proposed for quantifying the risk associated with family history based on the number of family members affected, the degree of closeness of their biological relationship to the individual under consideration, and their ages at onset of disease (Yoon et al. 2002). From this information about their relatives, it is suggested that people can be stratified into average-risk, moderate-risk, and high-risk groups, and given appropriate preventive advice (Khoury et al. 2005). Those at average risk would be encouraged to adhere to standard public health prevention recommendations. Those at moderate or high risk would be given personalized recommendations including, for example, assessment and modification of risk factors, lifestyle changes, alternative early detection strategies, and perhaps chemoprevention. Those at high risk would also be referred to the specialist clinical genetics service to investigate the possibility of a high-penetrance genetic disorder. Although only a few people are expected to fall into the high-risk group, a much larger number will be assessed as being at moderate risk, offering the possibility of augmenting and improving the standard population approach to prevention.

Risk stratification based on family history is already in clinical practice as a form of triage for individuals concerned about a family history of some common cancers, such as breast/ovarian and colorectal cancer (see, for example, guidelines of the United Kingdom's National Institute for Health and Clinical Excellence (2006) for management of women with a family history of breast cancer and Doerr and Teng (2012) for primary care applications). This approach is not, however, used proactively as a screening programme.

The added value of the proactive use of family history risk-stratification as an adjunct to population-level prevention activities needs rigorous evaluation (Khoury et al. 2005, 2010b). Issues that must be addressed include the degree of accuracy of family history reporting, the optimum algorithm for stratifying risk, and the value of family history as a motivator for behavioural change. Particularly rigorous evaluation will be needed if a positive family history is used as an indication for any preventive intervention that carries risk, such as chemoprevention. Health service providers, particularly family practitioners, will need education and training in taking and assessing family histories, and provision must be in place for effective follow-up of individuals who fall into higher-risk groups. Health economic analysis should also form part of the overall assessment of the family history approach.

Genetic and genomic tests in clinical practice

Genetic and genomic tests may be used in clinical care for various purposes, including diagnosis of a disease, prognosis, assessment of disease risk, and prediction of response to a therapeutic (e.g. drugs) or preventive (e.g. vaccines) intervention (Burke et al. 2007; Teutsch et al. 2009).

Diagnostic genetic tests

Diagnostic genetic tests may be used to detect a DNA or chromosomal variant (or variants), or pathognomonic metabolic changes, associated with a disease. For example, in an infant with

ambulatory problems, a DNA test may confirm a diagnosis of Duchenne muscular dystrophy. Often a diagnosis of a genetic disease provides important prognostic information as well. Where specific treatments are available, diagnosis may provide an essential guide to treatment. For example, a diagnosis of haemochromatosis provides information about the need to manage iron stores to prevent diseases associated with iron overload.

Risk assessment

Risk assessment is also an important tool in clinical practice: family history, as discussed earlier, provides an important risk assessment tool, and when family history suggests increased risk, genetic testing may offer an opportunity to identify specific individuals at high risk who would benefit from aggressive prevention efforts—e.g. BRCA testing to identify women with a high risk of breast and ovarian cancer.

Predictive genetic tests

Because an individual's germline DNA remains largely unchanged throughout life, DNA testing can in some circumstances be used in an asymptomatic individual to predict the risk of a specific genetic disease occurring in the future. The classic example is Huntington's disease, which may be predicted with almost 100 per cent certainty by a DNA test even before birth. A positive test result for a pathogenic mutation in the *APC* gene associated with familial adenomatous polyposis, an inherited form of bowel cancer, predicts future disease with 90–100 per cent certainty. In the context of highly penetrant Mendelian conditions, predictive testing is sometimes termed *presymptomatic testing*. However, this high degree of predictive value is rare. Huntington's disease has a population prevalence of about 1 in 20,000–40,000, and fewer than 0.5 per cent of bowel cancer cases are thought to be due to inherited mutations in the *APC* gene. In relation to common disease, the predictive value of DNA test information is much lower; such tests may be better described as susceptibility or predispositional tests.

Pharmacogenetic tests

Heritable genetic factors are known to result in marked person-to-person and population variability in drug effectiveness and safety. With origins in advances in biochemical genetics in the first half of the twentieth century, the field of pharmacogenetics examines these variable responses to drugs. For example, variants of genes encoding members of the cytochrome P450 family of drug metabolizing enzymes affect dosage requirements for a wide range of drugs including warfarin, codeine, clozapine, timolol and abacavir (Sim and Ingelman-Sundberg 2011; Warnich et al. 2011). The concept underlying pharmacogenetics is that it may be possible to use DNA testing, be it genotyping or gene expression analysis, to tailor drug prescribing to an individual's genetic make-up, thereby optimizing response and minimizing adverse reactions. The path from discovery of a validated polymorphism influencing drug response to a clinically useful pharmacogenetic test is a complex one. The anticoagulant drug warfarin provides an instructive example. Warfarin dose requirement is affected by variation in both the *CYP2C9* gene through effects on its pharmacokinetics, and in the *VKORC1* gene through effects on its molecular targets (Sanderson et al. 2005; Eriksson and Wadelius 2012). However, other factors such as age, sex, other genes, gene–gene

and drug–drug interactions also affect warfarin response (and response to most other drugs). Further prospective studies in real-life clinical settings will help discern the extent to which *CYP2C9* and *VKORC1* testing might offer appreciable advantages over current best practice in warfarin prescribing, which includes careful clinical evaluation of the patient and post-prescription therapeutic drug monitoring.

Proposed pharmacogenetic tests need careful consideration based on intended clinical scenarios, including determination of diagnostic performance indicators such as sensitivity, specificity, positive and negative predictive values, and cost-effectiveness. The optimal parameters for a pharmacogenetic test will vary for different test indications. Pharmacogenetic tests for heritable variants remain mostly at the research stage but some somatic pharmacogenetic tests are already in clinical use, particularly in oncology. An example is the typing of *HER2* gene expression in breast tumours to test for responsiveness to the drug Herceptin® (trastuzumab), an antibody drug that targets the HER2 protein on the surface of tumour cells.

Gene expression profiling is under investigation as a tool to guide optimal treatment. For example, patients whose tumour gene expression profile, together with standard clinical criteria, indicates a good prognosis and a low probability of metastasis may be spared debilitating aggressive treatment with adjuvant chemotherapy. Gene expression profiling needs further evaluation before adoption for mainstream use in clinical pharmacology and therapeutics. In all, pharmacogenetic tests signal an expansion in the scope of genetic testing to address inter-individual differences in outcomes of health interventions such as drug therapy, in addition to disease susceptibility and prognosis. As we discuss later in the chapter, the emerging subspecialty of vaccinomics is yet another example of application of knowledge on human genomic variation to optimize health interventions.

Diagnostic genomic biomarkers

Genomic biomarkers such as gene expression, proteomic, or metabolomic profiles convey information about the molecular-genetic characteristics of somatic cells that may be correlated with clinical parameters such as disease staging, prognosis, and response to therapy. A hallmark of these data-intensive ‘omics’ biomarkers is that they offer a systems perspective on the informational value of a test, over and above the biological redundancies (e.g. overlapping metabolic pathways) preserved throughout the course of human evolution (Haring and Wallaschofski 2012). By contrast, biomarkers that target a singular pathway may incorrectly over- or underestimate their attendant predictive value. Gene expression and proteomic profiling remain an active area of clinical research, particularly in oncology, in part owing to ready availability of tumour biopsy specimens required for gene and protein expression analysis. Data on differences in regulation of gene expression is emerging as an important factor in health outcomes (Osman 2012), and this approach is postulated as an important avenue for identification of clinically useful biomarkers and, ultimately, new therapeutic approaches (Tian et al. 2012). Difficulties that need to be overcome include inadequate reproducibility, lack of standardization, failure to demonstrate improved outcomes as compared with current clinical practice, and poor positive predictive values, especially when used as screening tests in a population setting. Systematic approaches to ensure adequate validation of new tests have been proposed (Institute of Medicine 2012).

Reproductive genetic testing

Genetic testing also offers options for the assessment and management of reproductive risk. Diagnostic DNA tests carried out before birth (preimplantation or antenatal genetic diagnosis) may be used by couples at risk of transmitting a specific genetic disease to determine whether the embryo or fetus is affected by the disease. The purpose of testing is to enable the couple to exercise reproductive choice by either preparing for the birth of an affected child, opting to terminate a pregnancy, or, in the case of preimplantation diagnosis, choosing unaffected embryos to establish a pregnancy.

A special category of reproductive genetic test is a carrier test, which is used to detect a carrier of a Mendelian autosomal recessive or sex-linked disease. Individuals in families or populations affected by such diseases may wish to know whether they are carriers and therefore, although not themselves affected, at risk of transmitting the disease to their children.

Because decisions based on genetic information about reproductive risk are determined by personal values, these tests should not be recommended by health professionals. Rather, they are offered as an option, and the primary role of the health provider is to provide information and counselling so that prospective parents can make decisions about testing and follow-up that are most consistent with their goals and values. This testing therefore differs in its scope from testing intended to improve the health of the individual undergoing testing. Medical genetics has developed a supportive approach to counselling, focused on the educational and emotional needs of the individual or family seeking care (sometimes referred to as ‘non-directive counselling’) to address this practice need.

Evaluation of genetic and genomic tests

A US Task Force on Genetic Testing has defined a genetic test as ‘the analysis of human DNA, RNA, chromosomes, proteins, and certain metabolites in order to detect heritable disease-related genotypes, mutations, phenotypes, or karyotypes for clinical purposes’ (Holtzman and Watson 1997; see also definitions in Box 2.5.1). This definition implies that a genetic test is a test that enables a direct inference about the state of the germline genetic material. Any diagnostic test for a Mendelian disease or chromosomal disorder qualifies as a genetic test because it allows such an inference. For example, a renal ultrasound test for autosomal dominant polycystic kidney disease may be considered a genetic test because it enables the inference that there is or is not a lesion in one of the genes causally implicated in this disease. A biochemical analysis to detect haemoglobin variants causing sickle cell disease is also a genetic test. Any direct DNA test is a genetic test, whether it relates to a single-gene or chromosomal disorder, or to a low-penetrance genetic factor implicated in a common disease. However, a blood pressure test, for example, is not a genetic test by this definition because it does not enable any direct inference about the sequence or properties of a specific gene or genes.

The nature and implications of a genetic test can vary widely, depending largely on the penetrance of the condition or the genotype in question. It is important, when using the term genetic test, to be clear about whether it is being used to denote a test for a genetic (highly penetrant heritable) disease, or simply to mean a test of the genetic material (Zimmern 2001, 2014). A test for a genetic condition may have serious implications both for the person tested and for his or her blood relatives. In contrast, a test for

a common DNA polymorphism associated with susceptibility to, say, coronary heart disease will probably have no more serious implications for health than analysis of blood lipids, and no greater consequences for other family members.

The 1997 US Task Force's definition cited earlier, specifically excludes somatic genetic tests, such as tests of the genetic material in tumour cells or gene expression profiles in different tissues or organs. However, the development, use, and evaluation of somatic genetic tests—perhaps better termed 'genomic tests'—also pose both opportunities and challenges for public health. Somatic genomic tests may also include tests for other complex genomic biomarkers such as proteomic or metabolomic profiles.

Evaluation of genetic and genomic tests

Public health programmes have an important role in ensuring that any diagnostic, predictive, or pharmacogenetic tests used in health practice are properly evaluated in order to protect the public's health and assure validated health services. A genetic test (or any other clinical test) encompasses more than a laboratory assay. Rather, it is a complex process that is part of an overall regime of disease prevention or management for a specific individual in an intended clinical scenario (Kroese et al. 2004). A test is best conceived of as the application of an assay for a particular disease, in a particular population, and for a particular purpose (Kroese et al. 2004; Zimmern 2014). An assay may be deemed highly effective in one set of circumstances but not in another.

The first attempt to devise an evaluation framework for genetic tests was the ACCE evidentiary framework (Haddow and Palomaki 2004), using criteria originally proposed by the 1997 Task Force on Genetic Testing (Holtzman and Watson 1997). ACCE is an abbreviation standing for Analytical validity, Clinical validity, Clinical utility, and Ethical, legal, and social implications. It has been acknowledged that ethical, legal, and social implications such as potential discrimination, stigmatization, and psychosocial consequences form part of the assessment of the overall utility of a test (Grosse and Khoury 2006; Burke et al. 2010), and there has been a trend away from regarding them as a separable set of issues. Additionally, the scope of ethics is presently expanding beyond classic issues such as informed consent and protection of research subjects to examine the issues related to genomics evidence: which evidence, generated, synthesized and funded by whom, should be employed to adopt or reject genetic tests? (Özdemir et al. 2013a, 2013b).

Analytical validity

The analytical validity is the means by which an assay is evaluated. It is defined as the assay's ability to measure accurately (in the case of a genetic test) the genotype of interest. It is important to define the genotype precisely. A test to detect 24 specific mutations in the *CFTR* gene is not the same test as one designed to detect only four mutations, for example. The test characteristics will differ in these two circumstances because the reference standard will be different. A distinction can also be made between open-ended assays such as karyotyping (microscopic examination of the chromosomes) or mutation scanning across a gene, in which any abnormality is sought, and closed assays, which specify in advance the spectrum of mutations or abnormalities the assay is designed to test (Burke and Zimmern 2007).

Clinical validity

Clinical validity is the ability of a test to diagnose or predict a specific phenotype (usually, a specific disease); here, the reference standard is a clinical one. The clinical validity of a test encompasses more than a demonstration of good epidemiological association between a test result (the presence of a genetic variant) and the disease. There must additionally be a formal evaluation of test performance in practice.

For closed assays, parameters such as sensitivity, specificity, positive and negative predictive values, likelihood ratios, and the receiver operating characteristic (ROC) curve can be measured as diagnostic test performance. Even if there is a strong association between a genetic variant and a disease, as has been shown for the *TCF7L2* polymorphism and type 2 diabetes, a clinical test for this polymorphism may have very limited predictive value and thus poor clinical validity (Janssens et al. 2006).

Assessment of clinical validity is more difficult for open-ended assays because the sought after variants or their proxies are not known in advance, thereby raising challenges to estimate the clinical performance of an open-ended test. Microarray comparative genomic hybridization (CGH) offers an example (Subramonia-Iyer et al. 2007). CGH is a new technique for detecting submicroscopic chromosomal abnormalities, including some never detected before, and some that are unlikely to be of clinical significance. In this setting, measures based on biological plausibility can be used to estimate the likelihood that a detected abnormality is clinically significant (e.g. nature and location of the abnormality; whether similar chromosomal abnormalities have been described in normal populations). With the use of these parameters, the test can be evaluated for its estimated diagnostic yield (proportion of those tested with a positive result) and false positive yield.

Clinical utility

Clinical utility refers to the likelihood that a test will lead to an improved health outcome, by way of reduced mortality or morbidity or improved healthcare. Factors that may be considered include the clinical risks and benefits of testing, such as the availability of an effective intervention and the risks associated with any interventions (Burke 2002; Burke et al. 2002; Burke and Zimmern 2007), and health economic assessment.

Clinical utility may be poor if, for example, available interventions are not genotype-specific. Carriers of the Factor V Leiden or *G20210A* prothrombin variants have an increased risk for venous thromboembolism (VT). However, genetic testing of VT patients does not aid clinical management, as current evidence suggests that these genetic variants do not significantly increase the recurrence risk for VT.

Clinical utility has proved very difficult to assess in practice. Burke and Zimmern (2007), using criteria based on Donabedian's work (Donabedian 1978, 2005) on the quality of medical care, suggest that the main dimensions of clinical utility relate to the purpose for which a test is used (legitimacy, efficacy, effectiveness, and appropriateness), and the feasibility of test delivery (acceptability, efficiency, and the economic dimensions of optimality and equity) (Table 2.5.1). This approach has merit when looking at a utility from an objective population health perspective. However, one may also conceptualize utility as being primarily a subjective parameter, and that presented with the same data and evidence, individual citizens may interpret those data differently and take a different view as to the appropriate action for them as individuals.

Table 2.5.1 Key questions in genetic test evaluation

Domain	Questions
Assay	<i>How accurate is the assay?</i>
Analytical validity	What are the analytical sensitivity, specificity, PPV, and NPV of the assay, as compared to a gold standard?
Reliability and reproducibility	How reproducible are the test results under normal laboratory conditions?
Clinical validity	<i>What is the predictive value of the test in a defined population, for the specified disease?</i>
Gene–disease association	What is the strength of the association between genotype and disease? Is the genotype a minimally sufficient cause of disease? Is the genotype necessary for disease to occur?
Clinical test performance	What are the sensitivity, specificity, PPV, NPV, LR+, LR–, and ROC of the test, compared to a gold standard? If these measurements are not possible, what is the basis for proposing clinical validity for the test?
Clinical utility	
Test purpose	<i>What is the purpose of the test?</i>
Legitimacy	Is the proposed test in keeping with societal values, norms, and ethical principles? Is test delivery in compliance with laws and regulations?
Efficacy	Can the test and associated services achieve the intended purpose under ideal circumstances?
Appropriateness	What are the benefits and negative consequences of testing? Do the benefits sufficiently outweigh the negative consequences?
Feasibility of test delivery	<i>Can the test and associated services be delivered equitably, and in an acceptable manner, for a reasonable cost?</i>
Acceptability	Is the test delivered in conformity to the wishes, desires, and expectations of patients and their families?
Efficiency	Can the cost of the test and associated services be lowered without diminishing benefits? If there is an alternative for achieving the same purpose, is the test more or less efficient?
Optimality	What are the costs of the test relative to the benefits? Is a formal analysis of cost-effectiveness needed?
Equity	Can the test and associated services be provided equitably among different members of the population?

We note that the acceptable answers to the questions are context sensitive, and do vary across different tests, persons, countries and technology governance frameworks.

Reproduced from Burke, W. and Zimmern, R., *Moving beyond ACCE: An expanded framework for genetic test evaluation*, Paper prepared for the UK Genetic Testing Network, Copyright © 2007, with permission of the authors.

The full evaluation of a genetic test is a complex process that requires significant resources. Because it is not possible to apply the full process to all tests, different levels of evaluation may be applied, depending on the nature of the test, its purpose, and the population in which it is to be carried out. For example, most tests for rare disorders require a less stringent programme of evaluation than tests for common disorders or population screening. This is because, when penetrance is high, the association between a positive test and ultimate outcome is more predictable, and the rarity of the condition means that the number of tests will be small.

In the United States, an ongoing model initiative of the Centers for Disease Control and Prevention, the Evaluation of Genomic Applications in Practice and Prevention (EGAPP n.d.), is spearheading the integration of various models of genetic test evaluations including in-depth assessments and fast-track evaluation.

Evidence-based classification of recommendations on use of genomic tests in practice

As the number of genetic tests increases, the task to evaluate the available evidence has become ever more challenging and data- and labour-intensive, suggesting a need for a system to classify genomics applications with a view to their readiness for public health action. Those who produce evidence (e.g. genomics test

providers, scientists) and those who evaluate evidence (e.g. public health practitioners, regulatory scientists, social scientists) need to maintain an analytical distance for credibility and impartiality of decisions to transition (or not) candidate genomics applications to practice. The range of evidence taken into consideration may include prospective randomized controlled trials (RCTs) but often extend beyond so as to include observational and user-driven qualitative evidence, particularly on clinical utility of genomics tests. In addition, the existing binary (up or down) evidence-based recommendation for use of genomics tests often returns ‘insufficient evidence’ of clinical validity and utility for their use in clinical practice. The problem of insufficient evidence is not unique to genomics tests but is exacerbated by the lack of comparative effectiveness research (Khoury et al. 2010a). Binary or insufficient evidence recommendations do not permit refined decision-making, especially for clinicians who need to provide advice in the face of insufficient evidence. Khoury et al. (2011) have recently suggested a three-tier evidence-based classification of recommendations for use of genomic tests:

- ♦ Tier 1: ‘use in practice’.
- ♦ Tier 2: ‘promote informed decision-making’.
- ♦ Tier 3: ‘discourage use’.

The intermediate category of promoting informed decision-making is particularly notable because it provides interim guidance for clinical and public health practice. The framework for assigning genomics applications to one of the three tiers requires consideration, in the context of intended use, of the analytic validity, clinical validity and clinical utility of the test, and the existence of an evidence-based recommendation.

Tier 1 applications demonstrate analytic validity, clinical validity, clinical utility, and there are evidence-based guidelines encouraging their use.

Tier 2 applications demonstrate analytic and clinical validity, display potential for clinical utility (e.g. well-designed trials with appropriately selected endpoints are known to be in progress), but there are no evidence-based guidelines recommending clinical use.

Tier 3 applications have not yet demonstrated adequate analytic validity, clinical validity or clinical utility, or have demonstrated evidence of harms. The use of such applications is discouraged.

The CDC Office of Public Health Genomics provides a list of genomic tests and family health history in practice according to the three levels of evidence to researchers, providers, public health programmes, and others. As this list of applications is updated dynamically on an ongoing basis, we encourage the reader to consult with the attendant online source (Centers for Disease Control and Prevention n.d.).

Integrating genomics into public health practice

We are moving from an era in which genetics has been a small specialist clinical service dealing with patients and families affected by rare heritable diseases, to one in which genomic information and technologies may become a normal part of mainstream clinical and public health practice (Khoury et al. 2011; Zimmern 2011). During the past 10 years, public health professionals have begun to realize that this transformation must be rationally managed and to put in place organizations and steering strategies for achieving this aim. Introduction of genomics to public health practice requires multilayered evidentiary frames integrated across stakeholders, and from analytical validity to clinical utility and public health ethics dimensions.

The emergence of public health genomics

During the 1990s, some public health professionals in the United States and the United Kingdom began to realize that public health practice must take account of developments in genomics. In the decade since 1997, public health genomics has increased in strength and influence. A growing body of academic literature has established the intellectual foundations of the discipline. Groups focused on public health genomics have been set up within both government organizations (for example, the Office of Public Health Genomics, US Centers for Disease Control and Prevention, and the Office of Population Health Genomics in the Western Australian Department of Health) and academia (for example, centres at the Universities of Washington and Michigan and at Maastricht University).

Translation of genomics to public health practice is at the epicentre of the current life sciences R&D agenda, and can be expected to remain in focus for at least the next decade. The recent US National

Institutes of Health initiative to establish the National Center for Advancing Translational Sciences (NCATS) to pursue opportunities for disruptive translational innovation (Collins 2011) attests to the urgency of supporting translation science to move genomics to public health action. As we move towards an increasingly global science, public health genomics research and practice programmes with a similar mission and ethos need to be established in resource-limited settings in different countries. Conceivably, the existing genomics medicine networks can be scaled up so as to cultivate public health genomics in hitherto underrepresented global locales (e.g. Asia-Pacific, the Middle-East, Africa, etc.) and to ensure responsible integration of genomics to population health beyond a narrow technology-driven framework. Global expansion of public health genomics to developing countries and resource-limited settings is more than essential, to prevent a narrow technology lens in evaluation and implementation of genetic and genomic tests (Dandara et al. 2012; Özdemir and Knoppers 2013).

The Bellagio model for public health genomics

A multidisciplinary workshop convened in Bellagio, Italy proposed the following definition for public health genomics: ‘Public health genomics is the responsible and effective translation of genome-based knowledge and technologies for the benefit of population health’ (Bellagio Group 2005; Burke et al. 2006). This definition of public health genomics takes a population perspective to applications of new genome-based technologies to improve health. It focuses on prevention, evidence-based multidisciplinary science, and ethical, legal, and social implications, including addressing health disparities. The use of the term ‘genomics’ rather than ‘genetics’ signals that the subject matter is not confined to rare heritable diseases, and that much of the effort going forward will be directed at determining the contribution of genomic variants to disease pathogenesis using new genome-based technologies.

Building on this consensus definition, the Bellagio workshop developed a visual representation of the ‘enterprise’ of public health genomics (Fig. 2.5.3). The functions and activities shown in dark grey define the scope of the field. Several key features emerge from this representation:

1. The input to the enterprise is knowledge generated by genome-based science and technology, together with knowledge derived from academic research in the population sciences and practice on the ground, as well as the humanities and social sciences.
2. The driving force of public health genomics is knowledge integration. This term encompasses the activity of selecting, storing, collating, analysing, integrating, and disseminating knowledge, both within and across disciplines. It is the means by which genomics knowledge is transformed into ‘situated’ innovation that is contextualized for a given application, attuned to societal norms and hence, robust and sustainable (Ommer et al. 2011).
3. The integrated and interdisciplinary knowledge base is used to underpin four core sets of activities:
 - (a) Communication and stakeholder engagement (including, for example, public dialogue and involvement, and engagement with a broad range of genomics stakeholders for an

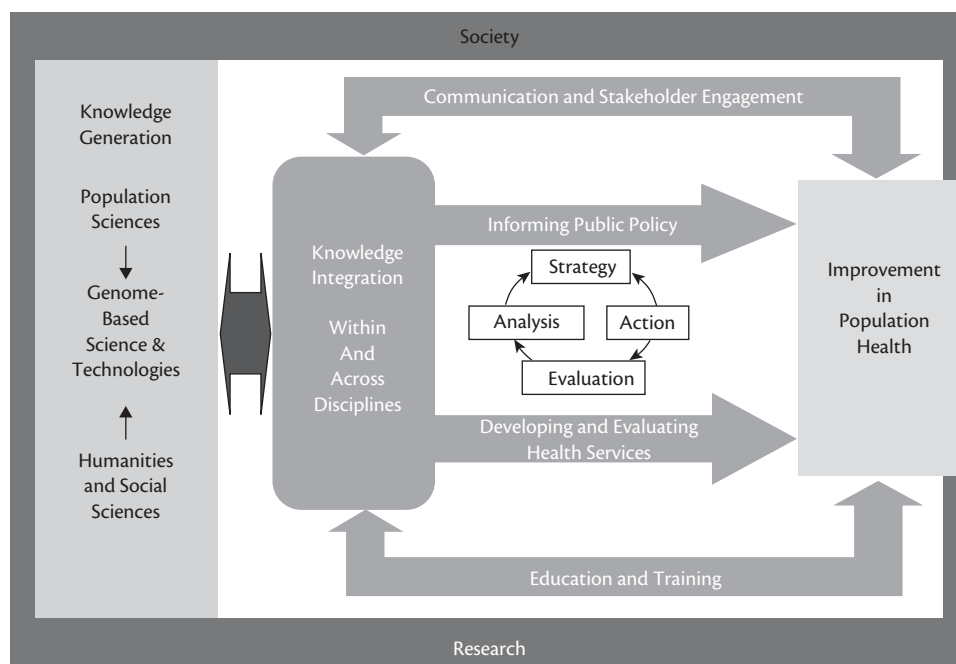

Fig. 2.5.3 The 'enterprise' of public health genomics. The scope of public health genomics is defined by the areas shown in dark grey.

- 'extended peer review' of genomics innovations in public health) (Özdemir and Knoppers 2013).
- (b) Informing public policy (including applied legal and policy analysis, engagement in the policy-making process, seeking international comparisons, and working with governments and other innovation stakeholders).
 - (c) Developing and evaluating health services (including strategic planning, manpower planning, and capacity building; service review and evaluation; and development of new programmes and services).
 - (d) Education and training (including programmes of genetic literacy for health professionals and generally within society, specific training for public health genomics specialists, and development of courses and materials).
4. The mode of working of public health genomics is described by the recursive cycle of analysis–strategy–action–evaluation–calibration/adjustment, which is a widely recognized representation of public health practice, and one that allows mutual dynamic learning among the innovation stakeholders.
 5. Public health genomics does include a research component defined in a classic sense, shown at the bottom of the diagram. This component is not generally basic research; rather, it is programmes of applied and translational research that contribute directly to the goal of improving population health and also identify gaps in the knowledge base that need to be addressed by further basic research. Hence, public health genomics is presently expanding the boundaries of classic notions of 'research' in that knowledge integration and bringing about 'change on the ground' are included. Ultimately, this is an invitation to rethink what is meant with 'research' and that the earlier mentioned hitherto underappreciated components are also *legitimate* building blocks of a research activity in twenty-first-century science.
 6. Public health genomics does not operate in a vacuum. It is embedded within a social and political context and is informed by societal priorities. In other words, public health genomics recognizes that scientific knowledge is 'socio-technical' in nature, and a co-product of both technology and the social/political systems whose boundaries are highly porous. For robust knowledge-based innovations, public health genomics advocates tackling the socio-technical systems attendant to knowledge co-production, not to mention the provenance of the trajectory from data to knowledge to action.
 7. Double-headed arrows throughout the diagram indicate the dynamic, bi-directional, and interactive nature of the enterprise: it generates knowledge as well as using it, and it is reflexively governed by the effects of its own outputs and activities.
- An international network, the Genome-based Research and Population Health International Network (GRaPH Int n.d.) has been established to support the development of public health genomics and the sharing of resources worldwide (Stewart et al. 2006). The administrative hub of the network was based in Montreal and funded by the Public Health Agency of Canada. Today, it is located at the University of Maastricht, the Netherlands.
- More recently, an international public health genomics meeting was held at Ickworth House, Suffolk, United Kingdom (Burke et al. 2010). The latter meeting has further endorsed the basis for public health genomics as the entire set of information stemming from the Human Genome Project and related environmental factors and data-intensive 'omics' sciences: not only gene sequences and gene–disease associations, but also information about the spectrum of gene expression activity, gene products and metabolites in different tissue types, and in normal and disease states (functional genomics, proteomics, and metabolomics) are taken into account.

'Big data' and vaccinomics for twenty-first-century vaccines

Twenty-first-century public health: data-intensive and collective innovation driven

'Big data' are now being sought to address the complex challenges we face in biology and other scientific fields such as global warming, climate change, and astronomy (Raddick and Szalay 2010). In the case of public health and biomedicine, the transition from genetics to genomics and other omics fields (proteomics, metabolomics, theranostics, etc.), new sensor and imaging systems to capture human phenotypic and biological variation, and attendant data-intensive simulation and computing have collectively resulted in a 'data deluge' in the twenty-first century (Smith et al. 2011; DaSilva et al. 2012; Özdemir and Cho 2012). Public health practitioners and life scientists increasingly have to deal with massive amounts of data in the order of petabytes (10^{15} = 1 million gigabytes = 1 thousand terabytes).

We are confronted with immense, globally distributed and heterogeneous datasets. Direct to consumer personal genomics tests that rely on big data (e.g. whole genome or exome sequencing for prediction of individual health risks) are bypassing the classic physician-centred health services and thus challenging the extant public health systems. Citizen-scientists also contribute to big data R&D, for example, in collection of high-granularity observations for ecosystem epidemiology where geographically distributed real-time science is crucial for human health. No longer are scientists forced to wait to generate data about human biological variation; instead, entire sets of scientific projects can be accomplished

with online data sources. Moreover, social media analyses generate copious volumes of data that reveal insights on spread of infectious diseases and other emergency-preparedness measures to be taken in support of population health (Merchant et al. 2011). For example, after the 2010 earthquake in Haiti, crowd-sourced information on an open-source Web platform has served well to link healthcare providers requiring supplies to those who had them (Ushahidi-Haiti at Tufts University 2010). In the 2009 influenza pandemic, health departments have tweeted and texted to direct the public to sites where vaccine against H1N1 influenza was available (Merchant et al. 2011).

With declining cost of genome sequencing and the current age of big data science, genomics has also breached *Moore's law*: the concept that the number of transistors (and by extension, computation and data storage and analysis capacity) on a computer chip doubles every 24 months, allowing 'chip scale' to be reduced proportionately. Consequently, the bottleneck in data-intensive fields such as public health genomics has shifted to that of addressing the issues pertaining to *data analysis and storage* instead of the past emphasis on *sequencing* or data generation alone (Figure 2.5.4).

A very recent exemplary application of the big data and collective innovation driven science that is currently impacting twenty-first-century public health is the ENCODE, the Encyclopedia Of DNA Elements Project. ENCODE aimed to describe all functional elements encoded in the human genome and announced its results on 6 September 2012, 9 years after its inception (ENCODE Project Consortium et al. 2012). While the Human Genome Project completed a decade ago provided the code for human genetic make-up, ENCODE provides deeper insights

Fig. 2.5.4 Declining cost of sequencing a human genome. Moore's law is the concept that the number of transistors (and by extension, computation and data storage and analysis capacity) on a computer chip doubles every 24 months, allowing 'chip scale' to be reduced proportionately. However, in the years from 2007–2011, the rate of reduction in human genome sequencing cost has far exceeded the data analysis and storage capacity defined by Moore's law.

on the *functional architecture* of the human genomics variation. Most importantly, ENCODE has now assigned more than 80 per cent of the human genome's components to at least one biochemical function (ENCODE Project Consortium et al. 2012). ENCODE has ramifications not only for modern biology and public health in the decades to come, it also firmly attests to massively collaborative science, collective innovation and dizzying volumes of data that increasingly define and shape twenty-first-century scientific practice.

No doubt, striking the right balance between data collection and analysis is the next grand challenge, as we move towards genomics applications for public health practice in the age of ENCODE and other similar big science projects.

Vaccinomics: designing the next generation of vaccines

The collective innovation and big data driven science is being exemplified in new subspecialties emerging within the field of public health genomics. Vaccinomics is one such prototype example. Vaccinomics represents the entry of data-intensive 'omics' health technologies such as genomics to the practice of vaccine science. Vaccinomics is a rapidly emerging frontier in genomics medicine and twenty-first-century public health. Much like pharmacogenetics, discussed earlier, it is based on the premise that genomic differences at the individual and population levels can be used to develop safe and effective pharmacological treatments targeted to subgroups in the population, the development of vaccinomics is based on genomic (as well as integrated proteomic and metabolomic) variations which regulate the host immune response and host–pathogen interactions to develop safer and more effective personalized vaccine strategies.

In a recent analysis of the new field of vaccinomics, Bernstein et al. (2011) noted 'despite the historic successes of vaccines, or perhaps because of these successes, vaccinology has evolved to rely almost entirely on an empirical, trial-and-error process, in which the pathways to protective immunity remain largely unknown'. Enabled with systems-oriented omics health technologies, vaccinomics offers unprecedented promise to transform vaccine R&D and health promotion in the twenty-first century, with novel vaccines for common infectious pathogens (e.g. tuberculosis, HIV, malaria) as well as therapeutic vaccines for NCDs (Fig. 2.5.5). By virtue of broad applications in both preventive and therapeutic contexts, vaccinomics brings about a broadening in the scope and ethos of vaccine-based health interventions. The US NIH Clinical Trials registry identifies over 20 clinical trials at Phase III stage for therapeutic cancer vaccines (O'Meara and Disis 2011). The first therapeutic cancer vaccine (Sipuleucel-T) for castration-resistant prostate cancer was approved by the US Food and Drug administration. The US National Comprehensive Cancer Network recognized this agent as a Category 1 (highest recommendation) in 2010 (O'Meara and Disis 2011).

Vaccinomics can be anticipated to grow as a new strand of public health genomics scholarship in the next decade. On the other hand, for big data-driven fields such as vaccinomics to have a concrete and compelling impact on population health, the entire data to analysis to innovation trajectory, as well as both people and technology, need to be connected in order to achieve a form of knowledge ecosystem and 'collective intelligence' that is far more effective than any individual or singular group of people and

Fig. 2.5.5 Vaccinomics guided design of the new generation of vaccines. Vaccine candidates can be identified by analysis of the pathogen's genome and/or pan-genome (the complete genetic content of the organism/species), transcriptome (the complete set of RNA transcripts), surfome (the complete set of expressed surface proteins), or secretome (the complete set of expressed secreted proteins), immunomics (the set of antigens that are recognized by the human or animal host), and vaccinomics (human responses to a vaccine). Finally, structural biology is expected to provide the first information to build prediction methods to identify protective epitopes.

computers. This seems essential given that vaccines and genomics have been met with both hope and pressures from funders and citizens to demonstrate their impacts for population health. Conflation of genomics and vaccine science in the form of vaccinomics offers much potential to engage with it at this early stage of the innovation trajectory, so as to steer it towards responsible innovation, one that is socially contextualized and subjected to 'extended peer review', as indicated earlier by the Bellagio model for public health genomics.

Genomics and public health ethics

The combination of genetics and public health has had an uneasy history, largely because of the legacy of the eugenics movement. Even today, there are still concerns about the potential tension between the population-level objectives of public health, the sensitive and personal nature of genomic information, and the priority that should be accorded to the autonomy of the individual citizen and the utility that he or she assigns to such information.

The traditional population-level approach of public health also raises another, more subtle, ethical problem in the era of genomic medicine: a reliance on the ethos of 'access' and 'provision'—for example, to essential diagnostics, medicines, and nutrition—but without due attention to the heterogeneity of the population to which these health-related services and goods are offered. It is important to allay these fears, which in many cases arise from framing of populations as a homogenous construct that may in turn compromise the ethical imperative to achieve optimum benefit from these interventions.

The legacy of eugenics

The term ‘eugenics’, literally meaning ‘well born’, was coined by Francis Galton in 1883. Its central philosophy was that the human gene pool could be ‘improved’ by selective breeding (Kevles 1995). Individuals judged to have a ‘good’ genetic constitution would be encouraged to have children, while those with ‘poor’ genes would be discouraged. The idea gained ground both in a number of European countries (including the United Kingdom and Sweden) and in the United States, despite ultimately discredited scientific backing. Some eugenic programmes involved the involuntary sterilization of large numbers of people deemed genetically ‘unfit’ because they were poor, homeless, or ‘morally degenerate’. In Nazi Germany, eugenic principles were invoked to justify the murder of millions of people.

Beyond the human rights abuses, an important lesson of the eugenics movement is that efforts to define ‘good’ or ‘bad’ genetic heritage are deeply flawed and problematic. Moreover, definitions of allegedly good and bad human characteristics falsely assume that they are merely a result of an individual’s genetics or autonomous moral agency; the acts and behaviours of human kinds are also co-produced by the ‘habitus’ wherein they reside, and the embedded power structures that interact with human agency (Bourdieu and Wacquant 1992; Rajan 2006; Özdemir et al. 2012). Even if ‘good’ and ‘bad’ traits could be defined, it would be impossible to select simultaneously for multiple ‘good’ traits and against multiple ‘bad’ traits. The eugenics movement has been rightly condemned, and repudiated in most countries of the world.

Use of genomic information: balancing the rights of individuals and society

Revulsion against eugenics has led to an insistence that genomic information is the property of the individual and his or her family. Individual autonomy, informed consent, and the privacy and confidentiality of genomic information have been paramount concerns. Numerous authors have warned about the dangers of stigmatization and discrimination against individuals on the basis of genetic characteristics.

Recently there have been attempts to re-balance the ethical debate and to move away from the concept that genetic information necessarily has a power and significance beyond that of other types of personal medical information—a concept known as ‘genetic exceptionalism’ (Murray 1997).

The development of applications for genomics to improve health will depend on the willingness of individuals to allow their genomic information to be used in population-based research projects designed to investigate low-penetrance genomic variants and genome–environment interactions that affect disease susceptibility. Concerns have been raised about the privacy and confidentiality of the genetic information of individuals participating in such projects. For example, full anonymization of samples and data may not be possible because the research may depend on the ability to link data to individuals. Moreover, the prospective nature of some epidemiological projects can mean that informed consent is difficult to implement fully: individuals may be asked to consent now to future uses of their samples and data that are currently unknown with additional data security and ethical oversight.

On the other hand, the ethical problems of large population studies may have been over-played. With appropriate protections in place, genomic studies are not likely to pose risks different from those people experience in their usual contact with the healthcare system and other entities that collect personal information. Although individual rights must be upheld, and genetic information must be protected just like any other personal data, community-centred ethical values such as solidarity, altruism, and citizenry must also be given due weight (Knoppers and Chadwick 2005). In this view, biobanks and population genomic research are seen as global public goods to be used for the benefit of current society and future generations (Knoppers 2005; Knoppers and Özdemir 2014).

These arguments do not deny the importance of high ethical standards for population-based projects and biobanking initiatives, in order to maintain the degree of public confidence that will be essential for the success of these long-term projects. Iceland’s deCODE project attracted criticism as a result of the Icelandic Government’s decision to assume that every individual in the country would be a participant in the project unless they specifically opted out, and to grant a commercial monopoly on any results from the project to the deCODE company. Other large-scale population biobanking projects have been more careful to avoid ethical controversy, for example, by establishing mechanisms for independent ethical oversight, paying careful regard to procedures for seeking informed consent from participants, and carrying out public consultations on project plans. Such measures appear to command broad approval although some disquiet persists, for example, over issues such as feedback of results to individuals, and terms for commercial access to samples and data. For the current biobanks initiatives around the world, the reader is referred to the international Public Population Project in Genomics (P3G) and Society (<http://www.p3gconsortium.org>). The P3G is also providing a platform for sharing best practice in ethical standards for biobanking initiatives.

Although procedures and norms for protection of individual research participants are well established, the potential for group harm from genomic research has received little attention, and represents an important area for both empirical and conceptual investigation. A qualitative study of stakeholder views related to genomic research in Africa identified a potential for group harm if the research involves populations already subject to stigmatization or addresses questions that have important ethical corollaries (de Vries et al. 2012). This concern points to the need for careful consideration of governance structures for data repositories, and, in particular, that the appeal to solidarity, altruism, and communal benefit is supported by vigorous oversight that ensures the use of data for societal benefit.

Population biobanks and databases are public goods; they are conceptualized as an unprecedented new configuration in twenty-first-century science—‘infrastructure science’—in contrast to the long-standing, single scientist-driven entrepreneurship frames on ‘discovery science’ (Schofield et al. 2010). Infrastructure science represents an invaluable resource for subsequent discovery-oriented science. Hence, we are presently witnessing a new dual reconfiguration of twenty-first-century data-intensive public health science exemplified by the coexistence of infrastructure science and discovery science (Rajan 2006; Özdemir et al. 2014).

Challenges and prospects for public health genomics

Integrating genomics into public health and behavioural research

Research is needed to strengthen the evidence base for applications of genomics in public health, particularly with respect to major public health problems such as obesity, outbreaks of infectious disease, or effects of exposure to environmental toxins and pollutants (Khoury et al. 2004, 2005; Evans and Khoury 2013).

Toxicogenomics and nutrigenomics

Toxicogenomics (sometimes referred to as ‘ecogenomics’) and nutrigenomics are important evolving areas of research that are attempting to unravel interactions between genomic variants and responses to toxic environmental agents and dietary constituents, respectively. There is good evidence that genomic variants do affect responses to these exposures but as with alleles associated with susceptibility to common disease, the predictive value of the individual risk alleles is generally low. For example, a polymorphism in the *DPB1* gene (part of the major histocompatibility complex, which encodes components of the immune system) increases risk of sensitization to inhaled beryllium dust, encountered by workers in the nuclear industry. However, although the relative risk conferred by the sensitizing *DPB1* allele is high (odds ratio ~10), the specificity of the *DPB1* marker is low, thus limiting its utility.

Many reported associations and gene–environment interactions in toxicogenomics and nutrigenomics have not been independently confirmed. For example, different studies have found opposite effects of the Pro12Ala variant of the PPAR- γ gene on the association between the dietary P:S (polyunsaturated:saturated fat) ratio and body mass index. Although non-replication can be due to poor study design, under-powered studies, and type 1 errors, these differences could also reflect true differences between the populations studied, as well as the known biological complexity of the role of PPAR- γ .

The fields of toxicogenomics and nutrigenomics are in their infancy, and it is likely that many years of research will be needed before validated evidence will be available to inform public health action. It is also important to ensure that this evidence, when it does become available, is used responsibly. Genetic effects on responses to environmental toxins or dietary components may identify some individuals or populations at high risk for whom specific preventive advice may be appropriate. Toxicogenomic and nutrigenomic research will also reveal important aspects of the biological mechanisms of interaction between environmental exposures and the human body. Such information could lead, for example, to better definition of the lowest tolerable dose for a toxin, based on the most susceptible genotype.

In terms of prevention, however, genomics is unlikely to supersede the value of standard public health advice for the bulk of the population. Public health practitioners must ensure that the benefits and risks of any proposed interventions or programmes based on toxicogenomics or nutrigenomics are carefully weighed, and that people are not misled by unsupported claims made by companies selling direct-to-consumer genetic test kits.

Infectious disease

The complete genomes of many important human pathogens have been sequenced, including those of the organisms implicated in tuberculosis, malaria, plague, leprosy, diphtheria, cholera, and typhoid. Genomic information is being used to develop new diagnostics, vaccines, and drug treatments (Warnich et al. 2011). For example, genomic technology and data-intensive omics sciences have provided important new leads for diagnosis of dengue fever in resource-limited countries (Ray et al. 2012). Research on the genome of the malaria parasite *Plasmodium falciparum* identified an unusual biochemical pathway for steroid synthesis and suggested that a drug (fosmidomycin) known to inhibit a crucial step in a similar pathway operating in bacteria and plants might be useful in treating malaria. Enabled by genomics, discovery of fosmidomycin is interesting because it is directed uniquely against *Plasmodium falciparum* malaria by inhibiting 1-deoxy-D-xylulose 5-phosphate reductoisomerase, an enzyme which is absent in humans (Umeda et al. 2011).

The process of infection involves not just the pathogen genome but also that of the host organism. The genomes of human populations have co-evolved with those of the pathogens that infect them, and resistance or susceptibility to infection has been a strong selective pressure in human evolution. A wide range of human genes, including the highly polymorphic genes of the immune system, are involved in human responses to pathogens. In some cases a single genetic variant appears to be significantly associated with susceptibility or resistance to a disease. For example, a specific polymorphism in the gene encoding the cell-surface receptor molecule CCR5 is associated with resistance to infection by human immunodeficiency virus (HIV). This candidate gene is of interest because the encoded receptor was known to be involved in entry of the virus into specific cells of the immune system. Analysis of genomic variants in resistant individuals may suggest new mechanisms and targets for drug development, or strategies for enhancing protective immunity in exposed populations.

Behavioural research

Public health programmes of disease prevention depend to a large extent on promoting behavioural change, but genomics has so far had little impact on behavioural research. It is particularly important, for example, that individuals who believe genetic testing has revealed they are at reduced risk from, for example, bladder cancer due to smoking, or coronary heart disease due to a high-fat diet, do not interpret ‘reduced risk’ as ‘no risk’.

In addition, the role of genomic factors in health-related behaviours must be more fully explored. For example, genomic factors are known to affect the likelihood that smokers will develop lung cancer, but the picture is incomplete without an understanding of the genomic factors that affect risk-taking behaviour and nicotine addiction. A fuller understanding of the role of genomics in human behaviour may suggest new strategies to promote public health and prevent avoidable death and disease.

The impact of genomics on epidemiology

Genomics offers new opportunities for epidemiological research. In time, the familiar 2×2 table correlating disease status (for example, in a case–control study) with the presence or absence of an exposure or risk factor may routinely be replaced by a 2×4

table in which the underlying genotype at a particular locus or groups of loci will be measured and evidence sought for interaction with the risk factor.

New tools and resources are being developed for epidemiological studies involving genomics. For example, as mentioned earlier in this chapter, genomics is inspiring the establishment of large population cohorts and ‘biobanks’ to provide resources for the discovery and characterization of genes associated with common diseases. In addition to promoting gene discovery, biobanks will help epidemiologists to quantify the occurrence of diseases in different populations and to understand their natural histories and risk factors, including gene–environment interactions. Large cohorts may also be used for nested case–control studies or case-only studies as an initial screening method. These studies will produce a large amount of data on disease risk factors, lifestyles, and environmental exposures, and they will provide opportunities for data standardization, data sharing, and joint analyses (Khoury et al. 2004; Davey Smith et al. 2005).

Genomic research may also help to identify unknown environmental risk factors for disease or confirm suspected environmental risk factors, through the approach of Mendelian randomization (Davey Smith et al. 2005). The reasoning behind this approach is that if a genetic polymorphism affects the level of a biological intermediate in a way that mirrors the effect of an environmental exposure on the same intermediate, and if the biological intermediate in turn affects disease risk, then an association between the polymorphism and disease risk can act as a proxy for the relationship between the environmental exposure and disease risk. Mendel’s law of random assortment of traits during transmission from parents to offspring means that this proxy relationship can be viewed as protected from the various confounding factors that affect observational studies of exposures.

The concept of Mendelian randomization can be illustrated by the example of the C677T polymorphism of the methylenetetrahydrofolate reductase (*MTHFR*) gene, which is needed for conversion of homocysteine to methionine (Khoury et al. 2005). The C677T polymorphism reduces *MTHFR* enzyme activity and increases levels of homocysteine, thereby mimicking the effects of low dietary folate intake. Thus a confirmed association between the C677T polymorphism and neural tube defects enhances causal inferences about the role of folate in neural tube defects. Although Mendelian randomization can potentially help epidemiologists derive better causal inferences about environmental exposures and disease, its application is currently limited by the paucity of confirmed genotype–disease associations, and incomplete understanding of the gene functions and biological pathways involved in the pathogenesis of common diseases.

Human genome epidemiology

Although thousands of gene–disease associations have been reported, only a small fraction of these have been independently replicated and fewer still can be considered fully validated (Khoury et al. 2007). Problems include publication bias, confounding by population stratification, faulty selection of control subjects, genotyping errors, deviations from Hardy–Weinberg equilibrium, linkage disequilibrium issues, misclassification of exposures and outcomes, inadequate statistical power, and type 1 errors (false positive associations). These problems point to a need for systematic evaluation and meta-analysis of studies to identify

validated associations, question unsubstantiated claims, and flag promising candidates for further investigation.

The Human Genome Epidemiology Network, HuGENet, is a global collaboration of individuals and organizations that develops methods and guidance for integrating and disseminating knowledge on the prevalence of genomic variants in different populations, genotype–disease associations, gene–gene and gene–environment interactions, as well as evaluating genetic tests for screening and prevention (Khoury 1999; Little et al. 2003).

HuGENet’s Web-accessible knowledge base captures ongoing publications in human genome epidemiology and is searchable by disease, gene, and disease risk factors. In collaboration with several journals, HuGENet also sponsors systematic reviews of the evidence on genotype–disease associations, using specific published guidelines for this work (the HuGENet handbook) as well as applying quantitative methods for evidence synthesis. Over 50 HuGENet reviews have been published on various diseases ranging from single-gene conditions to common complex diseases.

In 2005, HuGENet formed a network of investigator networks; these are mostly disease-specific research consortia that share knowledge, experience, and resources for human genome epidemiology investigations. The HuGENet Network of Networks has published a ‘road map’ for using consortia-driven pooled data and meta-analyses to augment the knowledge base on gene–disease associations (Ioannidis et al. 2006a, 2006b) and guidelines on the assessment of cumulative evidence on genetic associations (Ioannidis et al. 2008). HuGENet is also working on ways of integrating genetic epidemiological evidence on gene–disease associations with biological evidence.

Genomics in the developing world

Genomics and genomic technology will not replace traditional public health measures such as combating malnutrition, providing clean water and access to sanitation, alleviating poverty, and promoting sexual health. However, genomics offers potential benefits to the developing world, for example, in more rapid and accurate diagnosis of infectious disease (as discussed earlier in this chapter), enhancing the nutritional value of staple foods, bioremediation to reverse environmental degradation, and prevention of widespread human suffering by better recognition and management of genetic disease (Genomics Working Group of the Science and Technology Task Force of the United Nations Millennium Project 2004; Dandara et al. 2012).

It will be appropriate for different countries to adopt different strategies depending on the nature of their health problems, their economic situation, their social and political climate, their clinical and public health infrastructure, and the availability of trained medical and public health personnel. It is important to ensure that applications of genetics and genomic technology are thoroughly evaluated in pilot studies; that local expertise is fully engaged at all stages of the research, development, and implementation pathway; and that international aid is focused appropriately on developing local capacity, networks, and partnerships to cascade expertise and promote best practice. The appropriate targeting of global genomics research, in a manner that reflects the local and regional public health priorities, will remain an important challenge in the coming years. For example, in an analysis based on a PubMed-based systematic review of all the studies on human genetics that used Cameroonian DNA from 1989 to 2009, very few

studies dealt with public health-related genetic issues: only 10 per cent of the reports were related to haemoglobinopathies such as sickle cell anaemia despite its pressing public health importance (Wonkam et al. 2011).

Management and prevention of genetic disease

As mentioned earlier in this chapter, the developing world carries the heaviest burden of genetic disease, contributing to a birth defects prevalence that is 50–100 per cent higher than in the developed world (Christianson et al. 2006). The most prevalent genetic disorders in the developing world are the haemoglobin disorders (sickle cell disease and thalassaemia) and glucose-6-phosphate deficiency. Approximately 7 per cent of the world's population are carriers of a haemoglobin disorder, and 300,000–400,000 babies with severe forms of these diseases are born every year, mostly in tropical regions (Weatherall and Clegg 2001). The public health impact of haemoglobin disorders is substantial and in some regions is increasing, as falling rates of childhood mortality due to malnutrition and infection mean that more individuals survive to present for diagnosis and treatment. Demographic changes such as migration are also increasing the prevalence of haemoglobin disorders in the developed world.

Chromosomal disorders and multifactorial conditions with a strong genetic component also have a significant impact on the developing world. For example, lack of effective family planning, leading to high birth rates for older mothers, contributes to a significant birth prevalence for Down syndrome. Congenital heart defects and neural tube defects make a substantial contribution to childhood mortality and morbidity. High rates of consanguineous marriages in some societies may increase the birth frequency of rare recessive diseases.

As a first step towards improving management and prevention of genetic conditions, both low-income and middle-income countries should seek to educate their communities and health professionals about these conditions, promote family planning, improve maternal health and nutrition, and establish child health services (Christianson et al. 2006). If economic and political circumstances allow, it may be possible to establish a medical genetics service, including training appropriate health professionals in clinical diagnosis of genetic conditions and basic genetic counselling, and considering implementation of appropriate neonatal and antenatal screening programmes.

For sickle cell disease, the most cost-effective approach is likely to be the development of national centres with expertise in screening, DNA diagnosis, education, counselling, and management of the conditions (World Health Organization Advisory Committee on Health Research 2002). Ideally, such centres would support and train personnel for a network of peripheral screening clinics focusing on neonatal screening and administration of oral antibiotic prophylaxis in childhood, and taking the lead in programmes of public education.

The thalassaemias present a different range of problems. Simple and cheap diagnostic techniques are available to diagnose the condition and detect carriers. However, disease management is more complex and costly than for sickle cell disease because the severe forms require lifelong blood transfusion (using blood that has been screened to prevent transmission of pathogens) and expensive drug treatment to remove the excess iron introduced

by multiple transfusions. In some countries, programmes of antenatal carrier screening are considered acceptable to reduce the birth prevalence of disease. Once again, the model of centralized diagnostic laboratories and a network of peripheral screening clinics (in this case, for antenatal screening) may be appropriate. Antenatal carrier screening programmes have been in operation for many years in some Mediterranean countries, where as a result the birth frequency of beta thalassaemia has fallen by over 80 per cent (Cao et al. 2002).

In some middle-income, developing countries, such as the countries of South East Asia, changing lifestyles are leading to an increasing burden of disease from multifactorial conditions such as heart disease and diabetes, which may before long overtake communicable diseases as the major public health scourge in these countries. Although, as in the developed world, preventive strategies will be aimed at altering diet and lifestyle, some of the genetic variants underlying susceptibility to these conditions are likely to be population-specific. Genomic research in developing-world populations will be needed for a full understanding of the aetiology of disease and may point to a need for therapies and preventive interventions that are tailored for different population groups.

Genomic technologies in the developing world

In the wider sphere of genomic biotechnology, too, different strategies are appropriate for different countries (Genomics Working Group of the Science and Technology Task Force of the United Nations Millennium Project 2004). For some of the poorest countries, cheap genomics-based diagnostics may be cost-effective in programmes of infectious disease monitoring and control. International collaborations between the developed and developing world can help scientists in developing countries to gain access to appropriate technology, and to adapt this technology to a low-resource setting and a specific set of local conditions. Ongoing evaluation of any applications is also essential.

Some middle-income countries such as Cuba, Brazil, and Thailand are in a position to be able to develop their own biotechnology capacity. Governments in such countries need to create a favourable policy environment for genomic technology by investing in appropriate research, instituting transparent legal and regulatory frameworks and protection for intellectual property rights, stimulating their own biotechnology and pharmaceutical industries, and fostering public–private partnerships that are accountable to the public interest (World Health Organization Advisory Committee on Health Research 2002). Policies for applications of genomics and genetics must be sensitive to the ethical and cultural values of the country.

Training partnerships between industrialized and developing countries can help to develop human resources, and in some cases joint academic or clinical appointments can prevent the 'brain drain' of highly trained scientists and clinicians to more lucrative jobs in the developed world.

Education and training

In both the developed and the developing world, public health professionals must be prepared for the impact genomics will have on their practice (Austin et al. 2000; Burton 2003; Rajan 2006; Hotez 2011). As well as a working knowledge of basic genetics,

Box 2.5.2 Examples of some current initiatives in public health genomics

Centres

Office of Public Health Genomics, US Centers for Disease Control and Prevention

<http://www.cdc.gov/genomics>

Carries out research on how human genomic discoveries can be used to improve health and prevent disease. Established and coordinates the HuGENet (Human Genome Epidemiology Network) initiative.

Foundation for Genomics and Population Health (formerly the Public Health Genetics Unit)

<http://www.phgfoundation.org>

Multidisciplinary group that assesses advances in genetic science and their impact on health services and healthcare policy.

Centers for Genomics and Public Health

<http://www.sph.umich.edu/genomics/>

<http://depts.washington.edu/cgph/>

Established by collaboration between the US Centers for Disease Control and Prevention and the Association of Schools of Public Health, and located at the Universities of Michigan and Washington. The Centers contribute to the knowledge base, provide technical assistance to local, state, and regional public health organizations and develop and deliver training to the public health workforce.

Genomics, Health, and Society

<http://genopole-toulouse.prd.fr/index.php?id=57>

A multidisciplinary research centre located at the Toulouse Genopole, University of Toulouse, France, and including biologists, clinicians, geneticists, lawyers, sociologists, and economists.

Office of Population Health Genomics, Western Australian Department of Health

<http://www.genomics.health.wa.gov.au/home/index.cfm>

Aims to facilitate the integration of genomics into all aspects of public health, policy, and programmes.

Resources

HumGen

<http://www.humgen.umontreal.ca>

An international database on the legal, ethical, and social aspects of human genetics, developed as a collaboration between academia, government, and industry located at Faculty of Medicine, McGill University, Canada.

GDPinfo

<http://apps.nccd.cdc.gov/genomics/GDPQueryTool/default.asp>

A searchable database of all the documents available on the Office of Genomics and Disease Prevention Website, including the HuGENet database.

PHGU Genomics Policy Database

<http://www.phgfoundation.org/policydb>

A searchable web-based database of literature on policy development for genomics in health services and healthcare.

Projects

Evaluation of Genomic Applications in Practice and Prevention (EGAPP)

<http://www.cdc.gov/genomics/gtesting/egapp.htm>

The project aims to develop a coordinate process for evaluating genetic tests and other genomic applications that are in transition from research to clinical and public health practice.

P3G Consortium—Public Population Project in Genomics

<http://www.p3gconsortium.org/>

An international consortium to provide the international population genomics community with the resources, tools, and know-how to facilitate data management for improved methods of knowledge transfer and sharing.

Canadian Programme on Genomics and Global Health

<http://www.utoronto.ca/jcb/genomics/index.html>

Promotes the use of genomics and biotechnologies to improve health in developing countries.

HuGENet

<http://www.cdc.gov/genomics/hugenet/default.htm>

A global collaboration of individuals and organizations committed to the assessment of the impact of human genome variation on population health and how genetic information can be used to improve health and prevent disease.

they will need an understanding of human genome epidemiology and the criteria for evaluation of genetic tests, and an appreciation of the ethical, legal, psychosocial, and policy dimensions of applications of genomics and genomic technologies.

A set of competencies in genomics for the US public health workforce has been developed (US National Office of Public Health Genomics 2001). Competencies are documented for the workforce as a whole and for specific groups including leaders/administrators, clinicians, epidemiologists, health educationalists, laboratory staff, and environmental health workers.

In addition, some individuals will require an in-depth knowledge of public health genomics, for example, those involved in screening and other preventive programmes, health service development and evaluation, public health education, and policy analysis and development. Educational programmes in public health genomics are already underway at some centres.

Conclusion

While the full benefits of genomics for public health practice are likely to take many years to materialize, new technologies such as next-generation sequencing (NGS) have markedly reduced the cost and time (e.g. from 10 years to 1 week) required to sequence a genome (Raffan and Semple 2011). Moreover, NGS and other emerging high-throughput genomics technologies present an invitation to better understand the molecular basis of ‘missing heritability’ for traits that otherwise display a strong hereditary component. In particular the ‘common trait, rare variants’ hypothesis—an alternative (or complementary) to the hitherto prevailed ‘common trait, common variant’ hypothesis is now amenable for testing in clinical studies as we can more readily identify rare genetic variants with NGS. In the case of the ‘the common trait, rare variants’ hypothesis, multiple rare variants with moderate to high penetrances are assumed to collectively influence disease susceptibilities. Together with direct to consumer availability of NGS-driven personal genomics tests, this enhanced ability to characterize human genomics variation is blurring the boundaries between research and clinical practice (Dove and Ozdemir 2013, 2014a, 2014b; Petersen 2013), and creating a demand for more innovative frameworks to approach and evaluate clinical utility (Evans and Khoury 2013; Özdemir et al. 2013b).

In the course of these important changes brought upon by new genomics technologies and conceptual frameworks, public health genomics must take on the ‘steering’ role for the long-haul as knowledge strands converge and coalesce from public health and data-intensive genomics sciences (Halliday et al. 2004; Davey Smith et al. 2005; Zimmern and Khoury 2012). However, there is a need now to establish integrated and inter-generational capacity for both discovery and infrastructure science for the decades ahead. Leadership, sharing of resources (Box 2.5.2), and knowledge through international networks such as GRaPH Int and the Public Health Genomics European Network (PHGEN n.d.), programmes of professional education and training, and engagement with public policy development for genomics will all contribute to timely progress.

Ultimately, we need to rethink public health genomics as an effort to bring modern biology and science to public health to address population heterogeneity in disease and health intervention outcomes. In the absence of such knowledge, we risk a public

health practice that delivers inadequate and suboptimal responses to the extant disease burden in the population, not to mention health interventions such as drugs and vaccines with poor safety and effectiveness (Ozdemir 2014).

Water and sanitation

Thomas Clasen

Introduction to water and sanitation

Background

Safe drinking water and sanitary waste disposal are among the most fundamental of public health interventions. When readers of the *British Medical Journal* were asked in 2006 to name the ‘greatest medical advance’ since 1840, their top choice was clean drinking water and waste disposal, beating antibiotics, anaesthesia, vaccines, and germ theory (Ferriman 2007). Deaths from diarrhoeal diseases and typhoid fever showed dramatic declines in Europe and North America when cities and towns began filtering and chlorinating their water and safely disposing of human and animal excreta (Cutler and Miller 2005). The field of epidemiology arguably has its origins in John Snow’s nineteenth-century mapping of cholera cases and the eventual intervention at London’s Broad Street pump that demonstrated waterborne transmission of the disease.

While diseases associated with poor water and sanitation are now comparatively unknown in higher-income countries, they still impose a heavy burden elsewhere, especially among young children, the infirm, the poor, the immunocompromised, and the displaced. The World Health Organization (WHO) estimates that diarrhoeal diseases alone are responsible for 1.5 million deaths annually, including 760,000 among children under 5 years (WHO 2013). Diarrhoea is the third leading cause of deaths of children <5 years in low-income countries, accounting for 11% of the overall disease burden in this population. Improvements in water, sanitation, and hygiene have the potential to reduce this disease burden by an estimated 58% (Prüss-Ustün et al. 2014). As discussed below, poor water and sanitation is also associated with a heavy disease burden from malnutrition, parasite and worm infection, trachoma, and environmental enteropathy. Water and sanitation are not only a matter of public health, but also of poverty, equity, and justice (United Nations Development Programme 2007). Because they are less likely to have access to safe water and sanitation, the poor bear most of the burden of water-related diseases, driving them further into poverty through lost productivity and expenditure on treatment (Blakley et al. 2005). Time spent in collecting water from distant sources and the inability to procure sufficient quantities of water for irrigating crops, watering animals, and carrying out other productive activities aggravates poverty. While urban-rural disparities in water and sanitation coverage are well documented (WHO and UNICEF 2014), a recent analysis of sub-Saharan Africa also demonstrated important geographic inequalities in use of water and sanitation previously hidden within national statistics (Pullan et al. 2014). These results confirm the need for targeted policies and metrics that reach these marginalized populations.

(Pickering and Davis 2012). Inadequate water and sanitation are also associated with poor school attendance (Hutton et al. 2007). For these and other reasons, water and sanitation have been recognized as a fundamental human right (United Nations 2010).

Nevertheless, basic water security and sanitation still elude much of the world’s population living in low-income countries. An estimated 748 million people lack improved access to water supplies; hundreds of millions more rely on water that is unsafe for drinking (WHO and UNICEF 2014). An estimated 2.5 billion people—40 per cent of the world’s population—lack access to improved sanitation; more than 1 billion of those still practise open defecation. Coverage is lowest in developing regions, where people are most vulnerable to infection and disease. In sub-Saharan Africa, improved water and sanitation coverage is just 63 per cent and 30 per cent, respectively. Rural areas also lag behind their urban counterparts. By the end of 2011, 83 per cent of the population without access to an improved drinking-water source lived in rural areas. If current trends continue, more than half of the rural population will still be without sanitation coverage in 2015, and more than 700 million mainly poor rural dwellers will still lack improved water (WHO and UNICEF 2014).

The shortfall in water and sanitation coverage is not the result of a failure to recognize the need or declare goals at the highest international levels. The 1977 Mar del Plata Declaration by the United Nations (UN) expressed the goal of providing safe water and sanitation for all by 1990, launching the Water and Sanitation Decade (1981–1990) (Cairncross 1992). In 1990, the UN renewed the call and extended the deadline to the end of the century. The UN Millennium Development Goals (MDGs) call for halving, by 2015, the portion of the population without sustainable access to safe drinking water or basic sanitation (United Nations 2000). As the research described in this chapter suggests, such coverage would not only advance the environmental security targets under MDG 7, but also make contributions to reducing poverty (MDG 1), increasing primary education (MDG 2), promoting gender equality (MDG 3), reducing child mortality (MDG 4), and combating major diseases (MDG 6). In a further effort to attract attention to this deficit and additional priority to the sector, the UN General Assembly declared 2005–2015 as the Decade for Action, Water for Life (WHO and UNICEF 2005), and 2008 as the International Year of Sanitation. Proposals for post-2015 goals call for universal access to drinking water at home, schools, and clinics, greater progress on sanitation coverage, and improved equity in access (WHO and UNICEF 2014).

Traditionally, much of the work in water and sanitation has been undertaken by engineers and has consisted of infrastructural improvements. Low-cost community- and household-based

interventions, such as protected wells, boreholes, and communal stand pipes for improved water supplies, and various types of latrines, septic tanks, and composting systems for improved sanitation, have been largely conceived by and constructed with the assistance of engineers. There are numerous books, manuals, and other resources that describe these systems in detail, including Cairncross and Feachem (1993), the UK Department of International Development (1998), Davis and Lambert (2002), the quarterly *Waterlines*, and the World Bank Water and Sanitation Programme (WSP) 'Field Notes' (World Bank n.d.). Readers are encouraged to refer to such sources for details on the design, installation, and operation of such systems, technology innovations, and the programmatic challenges associated with achieving widespread use on a sustained basis.

This chapter focuses solely on the public health issues concerning water and sanitation. After introducing some basic terminology, it begins by describing the diseases associated with inadequate water and sanitation and their contribution to the overall burden of disease. It then presents evidence of the effectiveness of water and sanitation interventions to prevent such diseases, the economic implications (especially cost-effectiveness and cost-benefits) of such interventions, and some of the other non-health benefits associated therewith. Recent and emerging developments in water, sanitation, and health are then discussed, along with some issues relevant to water and sanitation interventions. The chapter closes with a discussion of some of the continuing challenges in water and sanitation.

Terminology

At the outset, it is useful to understand some of the terminology used in describing the diseases, transmission routes, and interventions associated with the water and sanitation sectors. Water-related diseases are sometimes classified according to their disease transmission routes as *waterborne* (ingested in drinking water), *water-washed* (associated with inadequate supplies of water for proper personal hygiene), *water-based* (transmitted through an aquatic invertebrate host), or linked to a *water-related vector* (involving an insect vector breeding in or near water) (White et al. 1972). Most waterborne organisms that are human pathogens colonize the gut of humans and certain other mammals and are transmitted through the *faecal-oral* route. The transmission of common waterborne diseases can thus be interrupted by improvements in sanitation (*excreta disposal*), personal hygiene (especially *hand washing with soap*), and microbiological *water quality*, while those that are water-washed are impacted by improvements in *water supplies* (quantity and access) for personal hygiene. Improving water supplies can also help prevent water-based diseases (such as schistosomiasis and dracunculiasis) by reducing the need to enter infected water bodies.

The term 'sanitation' is vague and has multiple meanings. Within the public health sector two definitions are used. Under the broader definition, sanitation extends to the process whereby people demand, effect, and sustain a hygienic and healthy environment for themselves. This definition could include safe food production, solid waste management, industrial waste, animal waste, control of chemicals, environmental pollution, storm water drainage, wastewater disposal, human settlements, personal and domestic hygiene, vector and vermin control, occupational health and safety, mining and quarrying, port health, and disposal of

the dead. A second definition is more specific, extending only to the process of separating humans from their excreta. This chapter uses this second, more specific definition and regards sanitation as a system in which excreta is: (1) collected safely and with dignity, (2) transported to a suitable location, (3) treated or contained to eliminate pathogenicity, and (4) reused and/or discharged to the environment.

The MDG targets for water and sanitation are expressed in terms of *sustainable access to safe drinking water* and of *basic sanitation*. The water target has been interpreted as 'sufficient drinking water of acceptable quality as well as sufficient quantity of water for hygienic purposes' (UN Millennium Project 2005). Basic sanitation, in turn, has been defined as 'the lowest-cost option for securing sustainable access to safe, hygienic, and convenient facilities and services for excreta and sewage disposal that provide privacy and dignity, while at the same time ensuring a clean and healthy living environment both at home and in the neighbourhood of users' (UN Millennium Project 2005). Progress toward the MDGs, however, is measured with reference to the Joint Monitoring Programme (JMP) that adopts an indicator approach based on facilities or level of service. For water supplies, the JMP distinguishes only between *improved water supplies* (piped-in tap water, public tap/standpipe, borehole/tubewell, protected well/spring, rainwater harvesting), and *unimproved water supplies* (surface water, unprotected well/spring, tankered water, bottled water) (WHO and UNICEF 2013). *Improved sanitation* includes a private flush or pour-flush toilet or latrine connected to a piped sewer system or septic system, simple pit latrine with slab, ventilated improved pit (VIP) latrine, or composting toilet; *unimproved sanitation* includes any other flush or pour-flush latrine, open pit latrine, bucket latrine, hanging latrine, any public or shared facility, or open defecation (WHO and UNICEF 2014). Some of these definitions are being reconsidered in the context of developing a set of post-MDG water and sanitation targets (WHO and UNICEF 2014).

Burden of disease

General

Poor water and sanitation are associated with a variety of infectious diseases transmitted through various pathways by helminths, protozoa, bacteria, and viruses. Table 2.6.1 summarizes the most important of these diseases, their transmission routes, aetiological agents, and epidemiological significance. Some of these diseases also contribute to malnutrition, a separate cause of substantial morbidity and mortality that is not reflected in the direct burden of disease figures cited in this chapter (Black et al. 2003).

Certain diseases associated with water are not addressed in this chapter. First, in addition to microbial agents, water is a medium for the transmission of chemical pathogens, including arsenic and other metals, fluoride, nitrates, and volatile organic compounds (including pesticides and herbicides). Accordingly, WHO guidelines and many national water standards establish maximum allowable limits for such chemicals (WHO 2012). However, except for arsenicosis and fluoridosis, which are especially serious in focal areas in Asia and parts of Africa, most of these contaminants represent hazards to health only over the longer term. Second, although improvements in water supplies (to discourage contact

Table 2.6.1 Principal infectious diseases, disease agents, transmission routes, and annual morbidity and mortality related to poor water and sanitation

Disease	Aetiological agent	Transmission	Infected ¹ (millions)	Mortality ¹ (thousands)
Diarrhoea (dysentery, cholera)	Virus <i>Rotavirus</i>	Faecal–oral	4000 (annual morbidity)	1400–1800
	Bacteria <i>Escherichia coli</i> (ETEC) <i>Shigella</i> spp. <i>Salmonella</i> spp. <i>Vibrio</i> spp. <i>Campylobacter</i> sp.	Faecal–oral		
	Protozoa <i>Giardia lamblia</i> <i>Cryptosporidium parvum</i> <i>Entamoeba histolytica</i>	Faecal–oral		
Schistosomiasis	<i>Schistosoma haematobium</i> <i>S. mansoni</i> <i>S. japonicum</i>	Penetration through skin exposed to contaminated freshwater	207	15–280
Ascariasis	<i>Ascaris lumbricoides</i>	Faecal–oral	1221–1472	3–60
Trichuriasis	<i>Trichuris trichuria</i>	Faecal–oral	759–1050	3–10
Hookworm infection	<i>Necator americanus</i> <i>Ancylostoma duodenale</i>	Penetration through skin exposed to faecally-contaminated soil Faecal–oral	740–1300	3–65
Typhoid and paratyphoid fever	<i>Salmonella</i> spp.	Faecal–oral	26	216
Trachoma	<i>Chlamydia trachomatis</i>	Fingers Clothing Eye-seeking flies (<i>Musca sorbens</i>) Coughing/sneezing	Blind from trachoma: 1.3 Active trachoma: 40 Trachiasis: 8.2	

Note: ¹ estimates vary according to method.

with water) and point-of-use water treatment (with filters) are important interventions in preventing dracunculiasis (Cairncross et al. 2002), efforts to control Guinea worm infection have been largely successful and the disease is now of public health interest in limited areas. Finally, this chapter does not address a variety of diseases associated with waterborne pathogens, such as poliomyelitis and hepatitis A and E, which are controlled mainly by vaccines and other non-environmental measures (Leclerc et al. 2002).

Diarrhoeal diseases

Diarrhoeal diseases represent the leading cause of mortality and morbidity associated with unsafe drinking water and poor sanitation. For those infected with the human immunodeficiency virus (HIV) or who have developed acquired immune deficiency

syndrome (AIDS), diarrhoea can be prolonged, severe, and life-threatening (Hayes et al. 2003). Diarrhoea is characterized by stools of decreased consistency and increased number. The clinical symptoms and course of the disease vary greatly with the age, nutritional and immune status, and the pathogen (Black and Lanata 1995). Most cases resolve within a week, though a small percentage continue for 2 weeks or more and are characterized as ‘persistent’ diarrhoea. Dysentery is a diarrhoeal disease defined by the presence of blood in the liquid stools. Though epidemic diarrhoea such as cholera and shigellosis (bacillary dysentery) are well-known risks, particularly in emergency settings, their global health significance is small compared to endemic diarrhoea (Hunter 1997). The immediate threat from diarrhoea is dehydration, a loss of fluids and electrolytes. Thus, the widespread

Fig. 2.6.1 The F-diagram.

promotion of oral rehydration therapy (ORT) has significantly reduced the case-fatality rate associated with the disease. Such improvements in case management, however, have not reduced morbidity, which is estimated at 4 billion cases annually (Kosek et al. 2003). And since diarrhoeal diseases inhibit normal ingestion of foods and adsorption of nutrients, continued high morbidity is an important cause of malnutrition, leading to impaired physical growth and cognitive function, reduced resistance to infection, and potentially long-term gastrointestinal disorders.

The infectious agents associated with diarrhoeal disease are transmitted chiefly through the faecal–oral route (Leclerc et al. 2002). Safe excreta disposal thus represents a primary barrier that should contribute to the prevention of indirect transmission via food, water, hands, fomites, and mechanical vectors (flies) (Fig. 2.6.1). A wide variety of bacterial, viral, and protozoan pathogens excreted in the faeces of humans and animals are known to cause diarrhoea. While the importance of individual pathogens varies among settings, seasons, and conditions, a recent multicountry study has shed important light on the principal aetiological agents responsible for much of the disease burden in Africa and South Asia (Kotloff et al. 2013). Investigators found that most attributable cases of moderate-to-severe diarrhoea were due to four pathogens: rotavirus, *Cryptosporidium*, enterotoxigenic *Escherichia coli* producing heat-stable toxin (ST-ETEC) and *Shigella*. *Aeromonas*, *Vibrio cholerae* O1, and *Campylobacter jejuni* were also important in selected sites. They reported that the odds of dying during follow-up were 8.5 times higher in patients with moderate-to-severe diarrhoea than in controls (odd ratio (OR) 8.5; 95 per cent confidence interval (CI) 5.8–12.5, $p < 0.0001$) and that 88 per cent of deaths occurred during the first 2 years of life. Pathogens associated with increased risk of case death were ST-ETEC (hazard ratio (HR) 1.9; 95 per cent CI: 0.99–3.5) and typical enteropathogenic *E. coli* (HR 2.6; 95 per cent CI: 1.6–4.1) in infants aged 0–11 months, and *Cryptosporidium* (HR 2.3; 95 per cent CI: 1.3–4.3) in toddlers aged 12–23 months. Although diarrhoea is also associated with the ingestion of metals, nitrates, organics, and other chemicals, the burden of disease arising from such exposure is small relative to infectious diarrhoea (Hunter 1997).

Schistosomiasis

Schistosomiasis affects 200 million people all over the world, with *Schistosoma haematobium* and *S. mansoni* being the most common species. The schistosomiasis life cycle involves contamination of freshwater by eggs carrying excreta and urine and an intermediate host, a freshwater snail. Larvae released in the water infect humans by penetrating through the skin. Parasites develop and migrate to the intestines and bladder where thousands of eggs are produced. Like other intestinal helminths, schistosomes are associated with impaired physical and mental development and anaemia. Furthermore, schistosomiasis may cause serious damage to the bladder and intestine walls as a result of parasite egg entrapment within tissues. Chronic infection with *S. haematobium* has been associated with increased risk of bladder cancer in adulthood (Gryssels et al. 2006).

Soil-transmitted helminth infection

More than 2 billion of the world's population are infected with soil-transmitted helminths. A disproportionate burden of helminthiasis occurs in marginalized, low-income, and resource-constrained regions of the world, largely in developing areas of sub-Saharan Africa, Asia, and the Americas (Lustigman et al. 2012). About 300 million people suffer from heavy worm load and related severe morbidity (deSilva et al. 2003). *Ascaris lumbricoides*, *Trichuris trichiura*, and hookworm (*Ancylostoma duodenale* and *Necator americanus*) are the most prevalent intestinal helminths. Transmission occurs via ingestion of eggs present in faecally contaminated soil, or via penetration of the larvae through the skin. Children are particularly vulnerable to chronic and heavy infections, which result in malnutrition, stunted growth, reduced physical fitness, and impaired cognitive development (Stephenson et al. 2000). Hookworm infection is an important cause of anaemia, not only in children, but also among women of reproductive age and pregnant women leading to premature birth and low birth weight (Hotez et al. 2004).

Typhoid and paratyphoid fevers

While enteric fevers such as typhoid and paratyphoid were leading causes of waterborne disease in previous centuries,

morbidity and mortality diminished dramatically with the provisions of disinfected water supplies and improved sanitary facilities (Cutler and Miller 2005). The aetiological agents for typhoid and paratyphoid fevers are *Salmonella enterica* serovar Typhi (formerly *S. typhi*) and *S. enterica* serovar Paratyphi A and B (formerly *S. paratyphi*). There are an estimated 21 million cases of typhoid annually, causing 216,000 deaths (Crump et al. 2004). The milder paratyphoid accounts for an additional 5 million cases each year.

Trachoma

Trachoma accounts for 15 per cent of world blindness, with 6 million people affected and 150 million at risk of visual impairment (Kumaresan and Mecaskey 2003). Trachoma is caused by repeated eye infection with *Chlamydia trachomatis*. Children are the main reservoir for infection, with high prevalence of active trachoma (Mabey et al. 2003). Repeated infections result in deformation of the upper eye lid, abrasion of the cornea, and progressive loss of vision in later life. *C. trachomatis* is transmitted from the discharge of an infected eye via contaminated fingers, clothing, and eye-seeking flies (*Musca sorbens*) (Hu et al. 2010). Although the role of flies in the transmission of infection remains unclear, studies have shown that *M. sorbens* breed mainly in solid human faeces present in the environment and not in latrines (Emerson et al. 2000). Thus, safe excreta disposal may play an important role in reducing trachoma transmission. Improving water supplies and sanitation is part of the WHO-backed SAFE (surgery, antibiotics, facial hygiene, environmental improvement) strategy for controlling and preventing the disease.

Malnutrition

Water and sanitation are also linked to malnutrition, a separate source of significant morbidity and mortality. An estimated 165 million children under 5 are stunted (i.e. have a height-for-age Z score of less than -2); 55 million children are wasted (i.e. have a weight-for-height Z score of less than -2), of whom 19 million have severe wasting (weight-for-height Z score of less than -3) or severe acute malnutrition (weight-for-height Z score of -3 or lower or associated oedema) (Bhutta et al. 2013). Child underweight or stunting causes about 20 per cent of all mortality of children younger than 5 years of age; it also contributes to long-term cognitive impairment, poorer performance in school, fewer years of completed schooling, and lower adult economic productivity.

Effectiveness of water and sanitation in preventing disease

Barriers to transmission of faecal–oral diseases

As illustrated by the so-called 'F-diagram' (Fig. 2.6.1), the safe disposal of human faeces is the primary barrier in preventing faecal–oral transmitted diseases. Without removing excreta from potential contact with humans, animals, and insects, pathogens may be carried on unwashed hands, in contaminated water or food, or via flies and other insects on to further human hosts. Whether or not sanitation is adequate, hands can become contaminated with faeces, especially during anal cleansing following defecation or in cleaning a child after defecation. This may result in further transmission, either directly or indirectly through food, water, or other beverages, or fomites. Accordingly, hand washing is an important secondary barrier to faecal–oral disease

transmission (Curtis and Cairncross 2003). Other secondary barriers include: (1) water quality interventions (e.g. safe distribution and storage or use of boiling or other point of use water treatment), (2) water supply interventions to increase the quantity and availability of water for personal and domestic hygiene, (3) proper cooking and food handling, and (4) control of mechanical vectors such as flies.

Evidence of effectiveness

Scores of studies have been conducted and published on the effectiveness of water, sanitation, and hygiene interventions to prevent infection and disease. Systematic reviews (Chapter 5.15) are a means of identifying, summarizing, synthesizing, explaining, and assessing the methodological quality of evidence of the effectiveness of health interventions with a variety of studies relating to a particular health intervention. In some cases, such reviews also employ meta-analyses or other statistical methods to estimate the pooled effect of the intervention across the studies included in the review. A number of such reviews have examined the evidence of effectiveness of water, sanitation, and hygiene interventions to prevent disease and infection.

Diarrhoeal diseases

Table 2.6.2 summarizes the results of five different systematic reviews of water and sanitation interventions to prevent diarrhoeal diseases published over the last 25 years. While there is conflicting evidence on the impact of water supply (quantity and access), there is consistent evidence that improvements in water and sanitation can make substantial contributions to the prevention of diarrhoeal diseases.

Soil-transmitted helminth infection

A more recent review assessed not only the impact of sanitation interventions on soil-transmitted helminth infections but also water and hygiene (Strunz 2014). The review covers 94 studies, though only 5 were randomized controlled trials. Use of treated water was associated with lower odds of infection from any soil-transmitted helminth (OR 0.46, 95% CI 0.36–0.60). Piped water access was associated with lower odds of *A. lumbricoides* (OR 0.40, 95% CI 0.39–0.41) and *T. trichiura* infection (OR 0.57, 95% CI 0.45–0.72), but not any STH infection (OR 0.93, 95% CI 0.28–3.11). Access to sanitation was associated with decreased likelihood of infection with any soil-transmitted helminth (OR 0.66, 95% CI 0.57–0.76), *T. trichiura* (OR 0.61, 95% CI 0.50–0.74), and *A. lumbricoides* (OR 0.62, 95% CI 0.44–0.88), but not with hookworm infection (OR 0.80, 95% CI 0.61–1.06).

In one systematic review, the authors reported larger protective effect of sanitation interventions to prevent soil-transmitted helminth infection despite acknowledging significant imitations (most studies used a cross-sectional design and were of low quality, with potential biases and considerable heterogeneity) (Ziegelbauer et al. 2012). Availability of sanitation facilities was associated with significant protection against infection with soil-transmitted helminths, with ORs ranging from 0.46–0.58 depending on the type of helminth. Pooling studies reporting on latrine use yielded ORs of 0.54 (95 per cent CI: 0.28–1.02), 0.63 (95 per cent CI: 0.37–1.05), and 0.78 (95 per cent CI: 0.60–1.00) for *Trichuris trichiura*, hookworm, and *Ascaris lumbricoides*, respectively. The overall ORs, combining sanitation availability and use, were 0.51 (95 per cent CI: 0.44–0.61) for the three soil-transmitted helminths combined,

Water supply (point-of-distribution)	37% (0–82%) (8)	16% (22)	0.75 (0.62–0.91) (6)	0.73 (0.53–1.01) (6)	0.98 (0.89–1.06) (8)	0.89 (0.78–1.01)
Water supply and sanitation/hygiene		20% (7)			0.43 (0.33–0.55) (3)	
Sanitation	22% (0–48%) (10)	22% (11)	0.68 (0.53–0.87) (2)		0.63 (0.43–0.93) (6)	0.84 (0.77–0.91)

Note: ¹ for studies by Esrey and colleagues, estimate of effect is the median reduction in diarrhoeal disease from the reported studies; for other studies, estimate of effect is the pooled risk ratio from meta-analysis using random effects model. To compare results, the percentage reduction is $1 - \text{RR}$ (e.g. RR of 0.69 implies a 31 per cent reduction in risk).

² Pooled estimates of effect in settings with unimproved water supply and prior to adjustment for non-blinding. For household interventions, estimates are for studies that combine treatment with safe storage.

0.54 (95 per cent CI: 0.43–0.69) for *A. lumbricoides*, 0.58 (95 per cent CI: 0.45–0.75) for *T. trichiura*, and 0.60 (95 per cent CI: 0.48–0.75) for hookworm.

Schistosomiasis

Esrey and colleagues (1991) reported a median reduction in the prevalence of schistosomiasis of 73 per cent (range 59–87 per cent) from four water and sanitation interventions; the reduction was 77 per cent among the three studies they deemed rigorous. Piped-in water supplies and community washing and bathing facilities that reduced contact with surface waters were especially protective, leading to reductions in both prevalence and severity (Esrey et al. 1991). The reviewers noted that in Kenya, the installation of boreholes without laundry or shower facilities failed to reduce infection.

Two quasi-randomized, controlled interventional studies from China also suggest that improved excreta disposal is protective against schistosomiasis. In a 3-year quasi-randomized controlled trial (RCT), Chen et al. (2004) recorded a 43 per cent reduction from combined water, sanitation, and hygiene interventions that also included a snail control component. Zhang et al. (2005) reported a 45 per cent reduction in a 2-year quasi-RCT that included water, sanitation, and hygiene. Once again, these trials did not include sufficient clusters to reliably calculate confidence intervals around the point estimates of effect.

Typhoid and paratyphoid

No RCTs of water or sanitation interventions to prevent typhoid or paratyphoid have been reported. A recent review of global trends in these enteric fevers identified little direct evidence of the potential contribution of water or sanitation interventions (Crump and Mintz 2010). Nevertheless, there is evidence suggesting the

effectiveness of water quality interventions. Cutler and Miller (2005) have shown the historical evidence on reductions in mortality associated with the introduction of clean water and sanitation in the United States. Case-control studies do suggest that the diseases are still associated with unsafe water and sanitation. In a study in Uzbekistan where typhoid remains endemic, cases were more likely to drink unboiled surface water outside the home (OR 3.0; 95 per cent CI: 1.1–8.20) (Srikantiah et al. 2007). In a similar case-control study in Bangladesh, drinking unboiled water at home was a significant risk factor (OR 12.1; 95 per cent CI: 2.2–65.6) (Ram et al. 2007). Among the risk factors for typhoid and paratyphoid in an urban setting in Indonesia were lack of a toilet in the household (OR 2.20; 95 per cent CI: 1.06–4.55) and use of ice cubes (OR 2.27; 95 per cent CI: 1.31–3.93). Enteric fevers are also a risk among travellers to endemic area, but effective vaccines are usually recommended against the risk of waterborne or food-borne transmission.

Trachoma

The evidence of the effectiveness of environmental interventions (including water and sanitation) alone to prevent active trachoma is not clear (Rabiu et al. 2012). Reviews of the WHO-backed SAFE strategy for trachoma control conclude that there is comparatively weak evidence of the effectiveness of the ‘F’ (facial cleanliness) and ‘E’ (environmental improvement) components that encompass improved access to water and better sanitation (Emerson et al. 2000a; Kuper et al. 2003). In a 6-month cluster RCT of 21 villages in the Gambia, Emerson and colleagues (Emerson et al. 2004) reported a reduction in fly catches among study clusters receiving latrines. However, the prevalence of active trachoma associated with the intervention was not statistically lower than among seven control clusters (RR 0.81; 95 per cent CI: 0.54–1.22). The study has not been repeated. In another review, access to

sanitation was associated with lower trachoma as measured by the presence of trachomatous inflammation-follicular or trachomatous inflammation-intense (TF/TI) (OR 0.85, 95% CI 0.75–0.95) and *C. trachomatis* infection (OR 0.67, 95% CI 0.55–0.78) (Stocks et al. 2013). Hygiene practices that require adequate supplies of water, such as facial cleansing, were also protective against trachoma. However, living within 1 km of a water source and the use of sanitation facilities was not found to be significantly associated with TF/TI.

Malnutrition

Malnutrition is linked to water and sanitation, both through food production (irrigation and safe use of waste for fertilizer) and by preventing diarrhoea and enteric infections that interfere with normal adsorption of nutrients (Fewtrell et al. 2007). An association of malnutrition with diarrhoea has been well established, but the impact of interventions is less clear. In a pooled analysis of nine studies with diarrhoea and growth data for 1393 children, the probability of stunting at 24 months of age increased by 2.5 per cent per episode of diarrhoea, and 25 per cent of all stunting in 24-month-old children was attributable to having five or more episodes of diarrhoea in the first 2 years of life (Checkley et al. 2008). The Maternal and Child Undernutrition Series in *The Lancet* estimated that sanitation and hygiene interventions implemented with 99 per cent coverage would reduce diarrhoea incidence by 30 per cent, which would in turn decrease the prevalence of stunting by only 2.4 per cent (Bhutta et al. 2013). A report for the World Bank suggests that open defecation explained 54 per cent of international variation in child height by contrast with gross domestic product, which only explained 29 per cent (Spears 2013). However, a recent systematic review and meta-analysis of water, sanitation, and hygiene interventions on nutritional status found no evidence on impact on weight-for-age Z-scores and only a small benefit on height-for-age Z-scores in children under 5 years of age (Dangour et al. 2013).

Economic implications of water and sanitation interventions

Cost-effectiveness and cost-benefit analyses

Hutton and colleagues (Hutton et al. 2007) assessed the cost-benefit ratios in 17 WHO epidemiological subregions of five categories of water and sanitation interventions based on the MDG water and sanitation targets and additional steps to minimize environmental exposure. The interventions included: (1) improvements required to meet the MDGs for water supply, (2) interventions to meet the water and sanitation MDG, (3) increasing access to improved water and sanitation for everyone, (4) providing disinfection at point-of-use over and above increasing access to improved water supply and sanitation, and (5) providing regulated piped water supply in house and sewage connection with partial sewerage for everyone. The study found that all water and sanitation improvements were cost-beneficial in all developing world subregions. The main contributor to economic benefits was timesaving associated with better access to water and sanitation services, contributing at least 80 per cent to overall economic benefits. A more recent analysis confirmed these results, concluding that the global return per dollar invested was \$5.50 for

sanitation, \$2.0 for water supply, and \$4.30 for combined sanitation and water supply (Hutton 2013). It estimated the global costs of universal access amount over the 5-year period 2010–2015 to US\$ 35 billion per year for sanitation and US\$ 17.5 billion for drinking-water.

A more recent economic analysis estimated the cost-benefit ratios of water quality (point-of-use filtration or chlorination) and sanitation (community-led total sanitation) interventions and placed them in the context of other comparable interventions (long-lasting insecticide treated nets and cholera vaccination (Whittington et al. 2012)). The study also found the water and sanitation interventions to be cost-beneficial. Most of the benefits, however, arose from improved health outcomes, principally reductions in mortality. Significantly, the study found substantial heterogeneity among the results; it also emphasized the sensitivity of the findings to assumptions about benefits, uptake, and usage. It cautions against generalizing the results to settings where the underlying assumptions about the population and the intervention can vary dramatically. It recommends decentralized decision-making and priority setting of water and sanitation in contrast to setting targets and subsidies by international organizations and large donors.

Willingness to pay; pricing strategies

Despite fairly consistent evidence that water and sanitation interventions are cost-effective and cost-beneficial, consumer demand varies with the type of products and services offered. Demand for piped water services in developing countries is especially inelastic (Nauges and Whittington 2009), even though their corresponding health benefits are not well established as noted earlier. This is likely to be due to the perceived value of timesaving. On the other hand, point-of-use water chlorination, though potentially among the most cost-effective of WASH interventions, has achieved only limited market penetration despite large-scale social marketing campaigns (Clasen 2009).

There is also continuing debate over user fees and subsidies to support the dissemination of interventions such as water and sanitation. Public health officials generally support free or heavily subsidized services, citing positive externalities, price elasticity, and the need to reach the lowest income households with services. On the other hand, water and sanitation officials as well as governments often insist on the need for user fees, noting the need for cost recovery strategies to ensure expansion and maintenance of services.

Cost-effectiveness analyses and cost-benefit analyses suggest that improvements in water and sanitation yield both health and other valuable benefits, not only to those who receive the intervention but also to the public sector. Inadequate water and sanitation services also have significant negative externalities (costs imposed on others), such as the costs of over-extraction from water supplies, pollution of water sources, and environmental degradation. Even those who promote water as a basic right accept that some value must be attached to water to reduce waste, encourage conservation, and promote higher value uses. Infrastructural improvements in water and sanitation often fail to be initiated or sustained because of a reluctance to charge fully for the cost of delivering the services, inefficiency in collecting such charges, or diversion of the fees away from operation and maintenance. Understanding who benefits from improvements in water and sanitation can help justify the allocation of costs and secure financing.

Fig. 2.6.2 Time travel (in minutes) versus consumption (in litres per capita per day).

Other benefits of water and sanitation interventions

Improving water availability (quantity and access)

As the section ‘Evidence of effectiveness’ suggests, improving water availability—even without a corresponding improvement in water quality—is associated with reductions of diseases transmitted through waterborne, water-washed, and water-based routes. This is partly due to the well-established relationship between the amount of water that people use and the time required to collect it (Cairncross and Feachem 1993). Fig. 2.6.2 shows the L-shaped curve that characterizes water consumption patterns based on service levels. While significant quantities of water are used if delivered directly to the home, the quantity used is fairly constant when the collection time is 5–30 minutes and further diminishes for longer collection times. In lower-income settings, average daily per capita consumption is about 150 L for those with household connections, 50 L for yard taps, and just 15 L for communal sources such as stand posts, wells, and springs. Thus, assessments of water availability are expressed in terms of distance: normally 1 km or round trip collection time (normally 30 minutes) (WHO and UNICEF 2013) but 0.5 km in disaster response (Sphere Project 2004).

A WHO report concluded that a minimum quantity of water for basic health protection is 20 L/person/day (Hutton and Bartram 2003). Of this, 7.5 L is for consumption (hydration and food preparation) and therefore must be of a quality to present minimal health risk; the balance is for basic personal and domestic hygiene. The report recognizes, however, that in addition to the direct health benefits associated with improving water supplies, there are indirect health and other benefits. Indirect health benefits may accrue from reducing the amount of time collecting water which can then be used more effectively at home caring for children or engaging in other productive activities (Cairncross 1987). Services at clinics, medical posts, and other healthcare facilities also benefit from improved water supplies. Sufficient water for irrigating gardens and crops can improve nutrition and generate income (Thompson et al. 2001). Vending water and making and selling beverages can also impact poverty. Finally, to the extent that people are paying for water, improved water supplies may result in savings that can be used for food and other necessities that may impact health outcomes.

Ecological sanitation

Within the sanitation sector there is an active group of advocates who promote the use of ecological sanitation (Winblad and Simpson-Hébert 2004). Ecological sanitation (EcoSan) works on the principle that urine and faeces are not just waste products, but assets that if properly managed, can contribute to better health and food production and reduce pollution. Managing such assets includes reducing pathogen loading to a safe level which is achieved by a combination of drying the faeces, increasing the pH, and storage for at least 12 months. Without good latrine management, pathogens can survive and create a risk to public health. The pathogen that causes greatest concern is *Ascaris*, which has a long persistence in the environment and a low infective dose (Cairncross and Feachem 1993). Public health risks need to be balanced against the potential benefits. In areas where land fertility is low, artificial fertilizer is expensive, and livelihoods are dependent on subsistence farming, the benefits of using excreta as a fertilizer/soil amendment could be considerable. Even when potential benefits can be demonstrated, local beliefs and taboos may limit acceptability or prevent adoption of the practice (Jackson 2005).

Improved school attendance

Although weaker than often asserted, there is some evidence that water and sanitation interventions at schools can improve school attendance, at least among girls (Freeman et al. 2012). This may be due to reduced incidence of disease resulting in fewer days of school missed as a result of illness. In Africa alone, Hutton et al. (2007) estimated that meeting the MDGs for water and sanitation would increase school attendance by 99 million days annually; full access to basic water and sanitation for all would increase school attendance by 140 million days each year. The sanitary needs of girls and the negative impact of lack of sanitation adversely impacts their attendance levels. In a recent trial in Kenya, schools with poor water access during the dry season that received combined water supply, hygiene promotion and water treatment together with improvements in sanitation experienced an increase in average attendance equal to 26 additional pupils per school on average (Garn et al. 2013). The proportion of girls enrolled in school also increased by 4%. In Uganda, 94 per cent of girls reported problems at school during menstruation and 61 per cent reported staying away from school (IRC International Water and Sanitation Centre 2006). Cultural and religious constraints in many settings make menstruation a taboo. If menstruation lasts over a week, there is a tendency for girls to skip the entire school year (Bharadwaj and Patkar 2004). Sanitation can play an important role in improving educational access for children with disabilities, through the improvement of paths, latrine floors, and installation of handrails (Bannister et al. 2005).

Security and gender equality

Improved sanitation and water supplies advance security and gender equality for women and girls. Household sanitation can increase their safety by avoiding the dangers of sexual assault and harassment faced when practising open defecation or using latrines away from their homes. Safe, private, and proximate latrines are now considered a basic human right (United Nations 2010); they are a particular issue for women in emergencies and conflicts (Sphere

Project 2004). Research in Kenya revealed that women would defecate into plastic bags and throw them into streets ('flying toilets') because they feared being raped when using latrines shared with men (Maili Saba Research Report 2005). They were also afraid of being seen to be using latrines too regularly and preferred to bathe within their own homes after dark where they felt safer. Young children often prefer open defecation due to fear of falling into pits in poorly-designed or unsuitably-adapted latrines.

HIV/AIDS

It is well known that access to safe drinking water and sanitation prolongs the lives of people living with HIV/AIDS (PLWHA) by reducing the risk of opportunistic infections, including diarrhoeal diseases (Peletz et al. 2013). Household-based water treatment has been shown to be an effective intervention in preventing mortality and morbidity in a population with one or more persons infected with HIV (Colford et al. 2005; Lule et al. 2005; Peletz et al. 2012). There is also evidence that household-based water filters and insecticide treated bednets for malaria slow the progression of HIV (Walson et al. 2012). Water and sanitation are now recognized as particular priorities in home-based care of PLWHA (WHO 2008). Point-of-use water treatment products are now included in health kits for people living with HIV/AIDS (Colindres et al. 2007). Efforts are also encouraged to ensure that mothers infected with HIV have safe drinking water (or point-of-use water treatment products) to prepare infant formula for use as an alternative to breastfeeding in order to minimize mother-child transmission.

Recent and emerging developments in water and sanitation

Post-2015 goals in water and sanitation

The MDG water and sanitation targets—to halve the proportion of the 1990 population without sustainable access to safe drinking water and basic sanitation—have been a major factor in mobilizing efforts to expand water and sanitation coverage. While there is still some controversy about JMP claims on the water target and overall disappointment on progress to the sanitation target, efforts are now underway to establish successor goals. As this chapter goes to press, it is still unclear what form these goals and the corresponding targets will take. However, recent proposals have included four possible targets: (1) by 2025, no one practises open defecation; (2) by 2030, everyone uses a basic drinking-water supply and handwashing facilities when at home, all schools and health centres provide all users with basic drinking-water supply and adequate sanitation, handwashing facilities, and menstrual hygiene facilities; (3) by 2040, everyone uses adequate sanitation when at home, the proportion of the population not using an intermediate drinking-water supply service at home has been reduced by half, the excreta from at least half of schools, health centres, and households with adequate sanitation are safely managed; and (iv) all drinking-water supply, sanitation, and hygiene services are delivered in a progressively affordable, accountable, and financially and environmentally sustainable manner (WHO and UNICEF 2014). In addition, there are proposals to change certain definitions used in monitoring these targets. A 'basic drinking-water supply' would include the JMP's current 'improved' water supplies (excluding protected wells or springs in urban areas) provided the time for collection/return does not

exceed 30 minutes. An 'intermediate' water supply would mean an improved drinking-water source on premises that delivers acceptable quantities at least 12 of the past 14 days of water with <10 cfu (colony-forming units) of *Escherichia coli* per 100mL. 'Adequate' sanitation would mean use of an 'improved' sanitation facility at home, and shared sanitation would be treated as 'improved' if it otherwise meets the required service level and was shared by no more than five households or 30 people. Future developments on the post-2015 water and sanitation targets can be followed by consulting the JMP website: <http://www.wssinfo.org/post-2015-monitoring/overview>.

Systems approach to understanding enteric pathogen transmission

Much of the research described in previous sections regarding the health impact of water and sanitation interventions has focused on assessing the impact of interrupting particular transmission pathways. Increasingly, epidemiologists are recognizing the interaction and interdependencies that characterize the transmission of enteric pathogens. This is leading to calls for a systems approach that not only acknowledges the multiple transmission pathways and varied aetiological agents involved in diarrhoea and other enteric diseases but also their dynamism and the community level impact of interventions (Eisenberg et al. 2012). Examples of this community effect are the health benefits that inure to non-adopters who live adjacent to households with latrines or who practise effective household water treatment. Interventions that interrupt transmission of one or more pathways can also impact transmission through other pathways of one or more pathogens. It is important that studies endeavour to capture externalities and the wider impact of an intervention at the community level, both to understand and design interventions that optimize this larger effect and to correctly assess the impact (and cost-effectiveness) of the interventions.

Water safety plans and microbial risk assessment

Traditionally, the water sector relied on compliance with end-product standards to ensure the safety of drinking water. Most drinking water standards are based on WHO guidelines that establish maximum limits for known or suspected microbial and chemical pathogens as well as physical/aesthetic characteristics. Under this approach, drinking water is to be free of pathogens at the point of delivery as demonstrated by the absence of a prescribed indicator of faecal contamination, such as *Escherichia coli* or thermotolerant coliforms (TTCs). However, the WHO adopted a risk assessment and risk management approach for improving drinking water quality (WHO 2012). The approach calls on water providers to develop and implement water safety plans similar to the hazard assessment critical control point (HACCP) approach used in the food industry to identify and control potential threats to safety. This latest rolling revision to the GDWQ also encourages greater surveillance to verify compliance.

This risk-based approach uses health-based targets for water quality. This is based on quantitative microbial risk assessment (QMRA), an approach developed for calculating the burden of disease from potential pathogens. QMRA sets pathogen limits based on the evidence concerning exposure assessment,

dose–response analysis, and risk characterization (Haas et al. 1999). Risk assessment and acceptable levels of risk are expressed in terms of DALYs. Reference pathogens are defined for each category of microbes. Significantly, these do not necessarily coincide with long-standing indicator organisms and may require capacity building in new laboratory techniques. Limited country-specific data and other resources may also delay full implementation of this approach in many countries.

Need for consistency/adherence in safe water consumption

Epidemiological modelling using QMRA has also been used to estimate the impact of sporadic exposure to contaminated drinking water, either as a result of interruptions in water supplies (Hunter et al. 2009) or from inconsistent use of point-of-use water treatment (Brown and Clasen 2012; Enger et al. 2013). The models show that in settings with moderately contaminated water supplies, much of the health benefit from improved drinking water quality is vitiated by even occasional consumption of untreated water. These results raise questions about the health benefits that can be gained from unreliable water supplies. Moreover, insofar as point-of-use water treatment campaigns often fail to achieve high levels of adherence, these models raise questions about the potential health benefits from household-based water treatment.

Wastewater reuse

QMRA is also used in the second edition of the WHO's *Guidelines for the Safe Use of Wastewater, Excreta and Greywater* for agriculture and aquaculture (WHO 2006). As an estimated 70 per cent of water withdrawals from surface and subsurface sources are used for agricultural purposes (Water Resources Institute 2007), the agricultural sector is particularly eager to develop safe, economical, and effective water sources for crop irrigation. Wastewater can be high in plant nutrients (nitrogen, phosphorus, and potassium), minimizing the need for chemical fertilizers and producing higher incomes for farmers (Ensink and van der Hoek 2007). As municipalities in lower-income settings struggle to treat even drinking water, however, few are able to remove potential pathogens from wastewater, leaving an estimated 80 per cent of sewage untreated. The WHO *Guidelines* attempt to balance the benefits of wastewater reuse with the need for food security. As treated wastewater is also being increasingly viewed as a potential source of drinking water in water stressed regions, additional guidance based on public health evidence will be necessary.

Household-based water treatment

For the hundreds of millions who lack household water connections that provide drinking water on a 24/7 basis, water is often collected and stored in the home until needed. It is well known that even water that is safe at the point of collection undergoes frequent and extensive re-contamination during collection (or compromised distribution), storage, and use in the home (Wright et al. 2004). While providing safe, piped in, disinfected water to each household is an important goal, even the purported achievement of the MDG water target leaves more than three-quarters of a billion people without access to improved water and hundreds of millions more without safe drinking water (Clasen 2012). Accordingly, the WHO and others have called for other approaches

that will accelerate the health and economic gains associated with safe water while progress is made in improving infrastructure.

Household water treatment and safe storage (HWTS) represent one such alternative (Sobsey 2002). Boiling, filtering, and chemically disinfecting water in the home are already in use, with more than 1 billion people reportedly treating their water at home before drinking it (Rosa and Clasen 2009). In many settings, both rural and urban, populations have access to sufficient quantities of water, but that water is unsafe. Because point-of-use interventions can improve the microbiological integrity of the water at the point of ingestion, they can reduce exposure if used correctly and consistently (exclusively) by a vulnerable population. Recent systematic reviews have shown household-based interventions (home-based boiling, chlorination, filtration, solar disinfection, and flocculation/disinfection) to be significantly more effective than traditional, non-reticulated source-based interventions (protected wells and springs, boreholes, communal tap stands) in improving microbiological water quality and reducing diarrhoeal disease (Fewtrell et al. 2005; Clasen et al. 2006; Waddington et al. 2009). The up-front cost of treating such water at the point-of-use can be dramatically less than the cost of conventional water treatment and distribution systems. Point-of-use water treatment, such as household-based chlorination, is the most cost-effective intervention to prevent diarrhoeal disease across a wide range of countries and settings (WHO and UNICEF 2002; Clasen et al. 2007). It is also among the most cost-beneficial (Hutton et al. 2007).

In 2003, the WHO helped organize the International Network for the Promotion of Safe Household Water Treatment and Storage, a global collaboration of UN and bilateral agencies, non-governmental organizations, research institutions, and the private sector committed to improved household water management as a component in water, sanitation, and hygiene programmes. The Network's website contains a considerable amount of information on household water management (http://www.who.int/household_water/en).

There is evidence, however, that the health impact from HWTS intervention trials may be exaggerated due to placebo effect and reporting bias. While more than three dozen studies of HWTS interventions reported a protective effect, none of the blinded studies that attempted to blind the intervention with a placebo found the effect to be statistically significant (Clasen et al. 2006). A large-scale double blind trial of chlorine tablets in India reported no impact of the intervention on diarrhoea or weight-for-height Z-scores in children under 5 years old (Boisson et al. 2013). This and other evidence of the lack of successful strategies for achieving adoption of HWTS interventions at scale has led some investigators to conclude that further efforts to scale up the intervention are not supported by the evidence (Schmidt and Cairncross 2009). Other investigators have noted, however, that if the estimates of effect of HWTS interventions are discounted by the exaggerated effect associated with open trials of reported outcomes (like self-reported diarrhoea), the interventions are still protective, particularly for those HWTS methods whose sustainability can be maintained (Hunter 2009; Wolf et al. 2014).

There is a need for additional assessments of HWTS interventions using placebos and objective outcomes in order to determine the actual protective effect of HWTS interventions to prevent diarrhoea. Even so, the size of the effect, if any, is likely to depend largely on the level of exposure, principal aetiological agent, other

potential sources of exposure, the efficacy of the HWTS method, the consistency of its use, and other factors that research may not yet have identified.

Shared and public sanitation

An estimated 450 million people—including a fifth of the population of sub-Saharan Africa and Eastern Asia—rely on public or other shared sanitation facilities (WHO and UNICEF 2013). Historically, such shared facilities are excluded from the definition of ‘improved’ sanitation for purposes of monitoring progress toward the MDG sanitation target, regardless of the level of service or number of people sharing them, because they are deemed unacceptable, unhygienic, and inaccessible. The JMP is currently considering a revision to this policy that would allow shared latrines to be considered ‘improved’ if they otherwise meet the required service level and are shared by no more than five households or 30 persons. However, there is little evidence to support this change. A systematic review and meta-analysis of 11 studies reporting on diarrhoea found increased odds of disease associated with reliance on shared sanitation (OR 1.39; 95 per cent CI: 1.14–1.70) (Heijnen et al. 2014). While there was some evidence of increased risk with the number of households sharing, there was an elevated risk at any level of sharing. An analysis of JMP data also found evidence of increased risk of diarrhoea associated with sharing latrines, even after adjusting for likely confounders (Fuller et al. 2014).

There are various reasons why observational studies might find shared sanitation to be associated with adverse health outcomes. These include differences in the underlying risk profile of people who rely on shared sanitation rather than individual household latrines, differences in latrine maintenance and use, increased exposure to pathogens circulating in the public domain, and differences in sludge management that increase community exposure. Shared sanitation is likely a necessity, particularly in high-density urban settings. It represents an increasing proportion of the types of sanitation on which populations in low-income settings rely. It is therefore necessary for research to determine whether shared sanitation actually increases risk, and if so, the reasons therefor and the interventions that can be implemented to mitigate any such increased risk.

Safe disposal of child faeces

While there are few published studies, the evidence suggests that in many low-income settings, nappies and potties are rarely available or used, making the hygienic collection of early child faeces difficult; if collected, such faeces are often disposed of in a manner that does not prevent further exposure (Gil et al. 2004). In fact, the unsanitary disposal of child faeces may present a greater health risk than that of adults. First, young children represent the highest incidence of enteric infections, and their faeces are most likely to contain agents. Second, young children tend to defecate in areas where susceptible children could be exposed. Third, young children who are also most at risk of mortality and the serious sequelae associated with enteric infection are most likely to be exposed to these ambient agents due to the time they spend on the ground, their tendency to put fingers and fomites in their mouths, and common behaviours such as geophagia. In a meta-analysis of ten observational studies published between 1987 and 2001, Gil et al. (2004) found that child faeces disposal behaviours considered risky (open defecation, stool disposal in the open, stools not removed from soil, stools seen in household soil, and children

seen eating faeces) were significantly associated with an increased risk of diarrhoeal diseases (relative risk (RR) 1.23; 95 per cent CI: 1.15–1.32); behaviours considered safe (use of latrines, nappies, potties, toilets, washing diapers) was borderline protective (RR 0.93; 95 per cent CI: 0.85–1.00).

There is evidence that even households with latrines often fail to dispose of child faeces safely; more commonly, they are either not collected or are disposed of with the household’s other solid waste (Majorin 2012). By definition, this renders the practice ‘open defecation’ even though these households are usually counted as having ‘improved sanitation’ due to the presence of the latrine (WHO and UNICEF 2013). Efforts to end open defecation will not be successful unless they include interventions to ensure the safe disposal of child faeces.

Technological and programmatic innovations

Steps to improve water supplies and sanitation, particularly in rural and remote locations, have proved especially challenging. Despite concerted efforts over past decades, vast numbers in Africa and South/South East Asia still lack improved water and sanitation (WHO and UNICEF 2014). While a variety of communal and household-level options have been promoted as alternatives to customary approaches in order to improve water quality, quantity, and proximity, some of these have been found wanting in terms of technological suitability, cost, and sustainability. New challenges include natural or man-made chemical contamination, saline intrusion, increasing urbanization, falling water tables, threats associated with climate change, and increasing demand for agricultural and industrial uses of water. High upfront costs, lack of financing, uncertain land tenure, inadequate skilled masons for construction, pit-emptying, longer-term waste disposal, and urbanization are major challenges in sanitation.

Public health professionals, donors, programme implementers, social entrepreneurs, and the private sector have responded to these challenges by developing and promoting a variety of technological and programmatic innovations for improving water supplies and sanitation, especially among low-income populations. In water, these include developments in rainwater harvesting, water locating, borehole drilling, well digging, locally-fabricated pumps and other water lifting devices, self-supply strategies, small community water treatment and/or distribution systems, water filling stations/kiosks, and a variety of point-of-use water treatment technologies. In sanitation, much of the effort in low-income settings focuses on improved on-site solutions in rural settings and alternatives to conventional sewerage in urban settings. Communal private latrines have been promoted widely in India and elsewhere. New technologies include cheaper, lightweight squatting slabs, composting toilets, digestion chemicals, multichamber pits, pit-emptying, and improved separation of liquid and solid excreta. Sludge is increasingly being viewed as a useful product rather than waste, with innovations in collection and processing. Many of these innovations are accompanied by entrepreneurial initiatives and public–private partnerships; others through micro-finance and base-of-the-pyramid marketing. While some of these innovations appear promising, lessons from the past suggest that understanding and responding to the particular circumstances present in a given setting—and especially what the target population itself wants and is willing to pay for—are especially important in achieving large-scale sustainable improvements that will also impact public health. Technical innovations in water and

sanitation that do not address the need for behaviour change are also unlikely to achieve optimal uptake and impact.

Water and wastewater testing and microbiology

American Public Health Association (APHA), the American Water Works Association (AWWA), and the Water Environment Federation (WEF) jointly publish *Standard Methods for the Examination of Water and Wastewater*, the definitive guide for water quality testing. The 22nd edition published in 2012 and available online (APHA et al. 2012) contains methods for assessing physical properties, metals, inorganic non-metallic constituents, aggregate organic constituents, individual organic compounds, radioactivity, toxicity, microbiological examination, and biological examination (APHA et al. 2012). Nevertheless, there are continuing debates about even fundamental issues, such as the use of indicators of faecal contamination such as coliforms, thermotolerant coliforms (TTC), and *Escherichia coli* (Gleeson and Gray 1997). The International Water Association's Health Related Water Microbiology Specialist Group is a rich source of research and new developments in the microbiology of water and waste, including water and wastewater treatment and its effects on health and the environment (including chlorinated by-products), methods in microbiology, microbe tracking and behaviour in water systems and the environment, rapid testing and monitoring, issues presented by bioterrorism, epidemiology and microbial risk assessment, and treatment processes.

Community-led total sanitation

First developed in Bangladesh in 1999 and expanding widely elsewhere, community-led total sanitation (CLTS) is an approach that empowers local communities to stop open defecation and to build and use latrines without the support of external hardware subsidies. Through the use of participatory techniques, community members analyse their own sanitation situation, including the extent of open defecation and the possibilities of faecal–oral contamination. This is designed to ignite a personal sense of disgust and shame that translates into collective action to reduce the impact of open defecation (Kar 2003). By triggering collective behaviour change, CLTS places the community, rather than the household, at the centre of the decision-making process. Peer pressure and civic pride are important motivating factors. The particular design of a latrine is secondary to the emphasis on 100 per cent coverage. The results can be impressive, with whole communities changing from open defecation to latrine use in a matter of months (Kar 2003). The approach has since been rolled out in Africa and Asia, and there is some evidence of its sustainability (Kar and Bongartz 2006). Nevertheless, the use of shaming and other social pressure to encourage latrine ownership is controversial (Bartram et al. 2012). Recent reconsideration of various aspects of the approach has resulted in proposed changes that are now promoted under the moniker 'CLST+'.

Sanitation marketing

Sanitation marketing uses a commercial approach to the production and delivery of sanitation technologies and engages the private sector for production and delivery in a financially and institutionally sustainable manner (Jenkins and Sugden 2006). Such a marketing approach has been recommended over typical

public-sector promotion of sanitation since it helps ensure that people choose to receive what they want and are willing to pay for, is financially sustainable, is cost-effective, and can be taken to scale (Cairncross 2004). Sanitation marketing adopts a consumer perspective, starting with an understanding of which products and services the target population wants, will pay for, will maintain, and are appropriate to the local context. It seeks to develop a sustainable sanitation industry, which is not dependent on external donors for hardware subsidies or long-term support for its continuation (Water and Sanitation Program n.d.). It recognizes the household as the key decision-maker regarding their defecation practice and the importance of effective public private partnerships. The extent to which the approach is capable of reaching the base of the economic pyramid has not yet been shown.

Scaling up sanitation; subsidies

Research has begun to explore the drivers and constraints toward latrine adoption (Jenkins and Curtis 2005; Jenkins and Scott 2007). Results demonstrate that while public health and economic benefits are the main societal reasons for investing in sanitation, householders have different reasons for wanting a latrine (Table 2.6.3). Research has shown that the rate of uptake of sanitation interventions increases as information spreads from one household to another, much like the adoption curves that characterize many new innovations (Cairncross 2004; Jenkins and Curtis 2005). Householder-perceived advantages of using a latrine become apparent as housing density starts to increase and when the need for privacy, convenience, and maintaining dignity become more important.

Subsidizing latrine construction is a controversial issue within the sanitation sector. Public incentives to private individuals are justified in an economic sense when there are externalities—social benefits that go beyond the private benefits associated with a given private action. As the public health benefits of limiting open defecation are greater than the private benefits an individual gains by choosing use of latrines over open defecation, sanitation may constitute a public good, thus justifying subsidies. However, for scaling up of sanitation to be successful, subsidies must be used to encourage householders to build and use latrines and help them overcome the constraints rather than to cover the actual costs of construction. Moreover, the public service priority needs to focus on safely and efficiently managing excreta within the larger community, especially in dense urban slums, after it has left the private domain of households (Evans et al. 2004; Methra and Knapp 2005). Inappropriately applied subsidies also have the negative effects of creating dependency, distorting the behaviour of the private supply market, and perhaps most importantly, not reaching the poor.

Enteropathy

Beyond the impact of diarrhoea on malnutrition, researchers have postulated that repeated exposure to faecal pathogens may be a significant cause of environmental (tropical) enteropathy, a sub-clinical condition characterized by malabsorption, villus atrophy, crypt hyperplasia, T-cell infiltration, and general inflammation of the jejunum (Humphrey 2009). Enteropathy is caused by faecal bacteria ingested in large quantities by young children living in conditions of poor sanitation and hygiene. Humphrey has suggested that the primary causal pathway from poor sanitation

Table 2.6.3 Inventory of stated benefits of improved sanitation from the private vs. public perspectives

Household perspective ¹	Society–public perspective ²
<ul style="list-style-type: none"> • Increased comfort • Increased privacy • Increased convenience • Increased safety, for women, especially at night, and for children • Dignity and social status • Being modern or more urbanized • Cleanliness • Lack of smell and flies • Less embarrassment with visitors • Reduced illness and accidents • Reduced conflict with neighbours • Good health in a very broad cultural sense, often linked to disgust and avoidance of faeces • Increased property value • Increased rental income • Eased restricted mobility due to illness, old age • Reduced fertilizer costs (ecological sanitation) • Manure for crop production (ecological sanitation) 	<ul style="list-style-type: none"> • Reduced excreta-related disease burden (morbidity and mortality) leading to: <ul style="list-style-type: none"> • Reduced public healthcare costs • Increased economic productivity • Increased attendance by girls at school (for school sanitation) leading to broad development gains associated with female education • Reduced contamination of ground water and surface water resources • Reduced environmental damage to ecosystems • Increased safety of agricultural and food products leading to more exports • Increased nutrient recovery and reduced waste generation and disposal costs (for ecological sanitation) • Cleaner neighbourhoods • Less smell and flies in public places • More tourism • National or community pride

(2002); Mukherjee (2000); Allan (2003); and Water and Sanitation Program (2002).² Reasons for public action stated in studies and documents but rarely quantified or ranked, see Evans et al. (2004); Jenkins and Sugden (2006).

and hygiene to undernutrition is tropical enteropathy and not diarrhoea. If so, current estimates may have substantially underestimated the contribution of sanitation and hygiene to growth because the effect is modelled entirely through diarrhoea. A recent study in Bangladesh found that markers of enteropathy linked to unhygienic environments (Lin et al. 2013). Further research is underway to assess the impact of water and sanitation interventions on this condition (Arnold et al. 2013).

Challenges in water and sanitation

Failure to treat diarrhoea as a serious disease

One of the threshold constraints to scaling up water and sanitation is the belief that diarrhoea—the main health threat associated with poor water and sanitation coverage—is not a disease. Figueroa and Kincaid (2010) cite numerous studies from various countries in which participants reported diarrhoea to be a natural and even desirable condition, especially in young children, not worthy of special preventative measures. Although health benefits often lack significant motivational impetus for driving preventative measures, the fact that diarrhoea is not even considered a disease by many of the most vulnerable populations further limits this strategy. Among policymakers and health officials faced with a variety of life-threatening diseases, diarrhoea may not receive the commitment of resources that its status as the third leading cause of morbidity and mortality from infectious disease would suggest it deserves.

Lack of public-sector coordination

In most countries, a variety of agencies and authorities are responsible for some part of water and sanitation. These typically include

the ministries of water, health, water resources, environment, local government, rural development, and education. In many cases, there are also federal, regional, district, and local levels of government. Rarely do any of these ministries take full responsibility for all aspects of water or of sanitation. The result is often a patchwork effort that lacks funding and coordination. There are important examples of successful coordinated public sector efforts. In South Africa, strides in sanitation are occurring because of a national decision and plan which set out targets, clear strategies, significant resources, and accountability (Muller 2002). Ethiopia has also achieved considerable success in improving water and sanitation coverage, particularly in the Southern Nations, Nationalities and Peoples Region, where a commitment at the senior levels translated into coordinated and sustained action (Bibby and Knapp 2007).

Bias toward large, infrastructural solutions

Public-sector advocacy, funding, and support has been shown to be an important factor in the successful scaling up of oral rehydration salts, insecticide-treated nets, and other interventions directed at environmental health. To date, however, governmental support for community and household-based water and sanitation interventions programmes has not been extensive in most countries. This is due in part to the engineering orientation of the applicable ministries, and their emphasis on larger-scale, infrastructural improvements, especially in urban and peri-urban settings. Nearly all populations who do not enjoy piped-in water on a 24/7 basis express priority for increasing the quantity and access to water over improving its quality. Governments respond accordingly, aware not only of the political value from these

popular projects (and the particularly photogenic value of water emerging from massive new pipes), but also the economic gains that are available from reducing the time people spend collecting and transporting water to their homes and from the productive use of water in agricultural activities. Multilateral and bilateral funding also tends to focus on such infrastructural water projects, despite compelling evidence that HWTs is more cost beneficial and highly cost-effective (Clasen et al. 2007; Hutton et al. 2007).

Uncertainty about the role of the private sector

Water and sanitation have traditionally been supplied by the public sector, particularly in Europe and North America where coverage, service levels, and costs are optimal. As governments, particularly in lower-income settings, have been unable to deliver services such as power, transportation, and even health and education to much of the population, they are increasingly relying on the private sector to provide such services. There are some apparent success stories where the private sector, through concessions, public-private partnerships, or other vehicles, enhances the coverage and service level of water and sanitation through increased investment and improved management of fee collection and delivery. At the same time, there are at least some notorious cases, such as Cochabamba, Bolivia, where a concession was opposed due to the perception at least that the private-sector partners were putting profits ahead of performance. There is certainly a need for regulation, as these services are usually a natural monopoly and market forces, if left unchecked, will favour delivery to higher-density and higher-income areas where paybacks are faster and costs/risks lower. The United Nations Development Programme (UNDP), World Bank, and others have examined the constructive role that the private sector can play in helping scale up the delivery of water and sanitation services (UNDP 2007). Balancing the potential contribution of the private sector against the needs of the target population will continue to represent a significant challenge for policymakers.

Decoupling sanitation from water

Since the 1990s, there has been an effort to always integrate water supply, sanitation, and hygiene promotion in developing countries within the same project. As a result, sanitation and hygiene have piggybacked on the political and community demand for improved water supplies. However, many effective interventions to improve excreta disposal do not require improvements in water supplies. While the water supply sector is dominated by engineers who lean towards technical solutions, sanitation, and hygiene promotion rely more heavily on understanding and changing behaviour, a different set of skills. As a result, staff in integrated projects naturally concentrate on water supplies, whilst excreta disposal fails to receive the resources it requires. The sanitation element is usually built around the process of providing the water supply; in fact, sanitation differs in that it requires a household rather than a community decision, requires more time, and is more complex from a behaviour change perspective. By decoupling sanitation from water, it may be possible to increase coverage more rapidly, particularly in remote areas in which water interventions are unlikely to reach in the near future.

Excreta disposal in urban unplanned areas

While urban areas generally have higher rates of sanitation than rural areas, the rapid growth of informal settlements

and urban slums presents a particular challenge for sanitation (WHO and UNICEF 2014). The lack of planning controls can result in ever increasing housing densities as plots are divided and subdivided either to house expanding extended families or to increase rental income. Eventually the area becomes saturated. This complicates excreta management in two ways: (1) streets and passages become very narrow making it impassable for latrine- and septic-emptying vehicles, and (2) the space available in each compound is insufficient to build initial or replacement latrines.

Another important and sensitive question with urban sanitation is the divide between public and private responsibility. Public funds are used to install, manage, and maintain public sewers and tariffs or taxation used to recover costs. No such publicly funded services are provided for the poor living in the unplanned high-density areas, and excreta disposal is regarded as being the sole responsibility of the household. It is arguable that the public health benefits from providing an appropriate pit emptying service could be so great that it warrants total public funding and provided free of charge to the poor.

Conflicting objectives in sanitation

Sanitation projects usually aim for a combination of four often-conflicting objectives. The first is to build a large number of latrines in a relatively short time, driven in part by the MDGs or national targets. In such cases, projects often use a supply-driven approach that coerces, entices, or persuades householders to build latrines by providing a generous subsidy, normally in the form of free hardware and/or labour. But when funding ends, the delivery and support mechanisms dissolve and the community members are left, as they started, with a lack of latrine component supply chains and nowhere to turn to for support. The second objective is to develop a sustainable sanitation industry that can continue providing latrines for many generations to come. This requires a good understanding of demand, the motivations and constraints of households in building and using latrines, and the use of marketing techniques to develop, promote, and supply better latrine components. This is a longer-term process which will not result in a large number of latrines being built in a short period of time and is therefore not attractive to politicians, donors, government officials, and implementers wanting instant MDG-driven solutions and to be seen to be doing something. The third objective driving sanitation is to enhance sustainable livelihoods and environmental improvements. This can be achieved by taking an ecological sanitation approach to latrine building which ensures that the nutrients in the excreta are reused to grow crops. The fourth objective is organizational insistence that their work must be targeted at the poorest of the poor. These are the most risk adverse, hardest to reach, price-sensitive members of the population who are also likely to be the least well educated and socially or politically connected. This makes them the least likely people to benefit from either a supply- or a demand-driven approach. While a targeted, sustainable, demand-driven, livelihood-enhancing latrine building programme that builds a large number of latrines in a short period of time is the ideal, decision-makers need to understand the weaknesses of each approach and prioritize their expectations accordingly.

Conclusion

Unlike many of the other challenges in public health, the solutions for eliminating most of the disease burden associated with poor water and sanitation are well known. All but the poor have enjoyed the health, economic, and other benefits associated with safe drinking water and basic sanitation for decades. The fact that hundreds of millions still lack access to these fundamental resources is a scandal that generations have allowed to persist simply as a matter of misguided priorities. And as the 'haves' continue to make rapid gains, they are not only increasing the gap over the 'have-nots' but also using up larger amounts of the world's limited water supplies and capacity for waste disposal, making it more difficult and costly for others to join their privileged club.

The need to extend water and sanitation coverage is acknowledged at the highest international levels, and progress is being made. Whether these efforts will be any more successful than those expressed in previous international declarations and goals is not yet clear. As the poor continue to wait for the piped-in water supplies and sanitary disposal that they deserve, however, it is incumbent on the public health community to develop, assess, and promote effective, low-cost, and sustainable alternatives and creative delivery strategies in order to accelerate access to the health gains associated with safe drinking water and basic sanitation.

Key points

- ♦ While safe drinking water and sanitation are widely recognized as fundamental public health interventions, more than a sixth of the world's population still lack improved water supplies and 40 per cent lack basic sanitation.
- ♦ The infectious diseases associated with unsafe drinking water and poor sanitation impose a heavy burden, especially on the poor, the very young, and the immunocompromised; they also aggravate poverty, education, and economic development.
- ♦ There is strong evidence that interventions to improve water supplies or sanitation can be effective in preventing diarrhoea, soil-transmitted helminth infections, schistosomiasis, and typhoid fevers.
- ♦ Water and sanitation interventions have also been shown to be cost-effective and cost-beneficial, with significant savings to the public sector from reduced healthcare costs; there is also evidence of other economic and developmental benefits from improved access to water and sanitation.
- ♦ A variety of recent and emerging developments, including new methods for assessing and monitoring the risk of diseases associated with water and sanitation as well as alternative technologies, programmatic approaches, and implementation strategies, may contribute to improved targeting, coverage, uptake, and sustainability.
- ♦ Nevertheless, significant political, social, economic, and developmental challenges must be addressed in order to successfully scale up some of these interventions on a sustainable basis and thus provide the most vulnerable populations with the health and other benefits of safe drinking water and sanitation.

Food and nutrition

Prakash S. Shetty

Introduction to food and nutrition

Food and the nutrients in it, habitually consumed by individuals, are important determinants of the health of populations worldwide. Nutrition and health interactions are complex and their determinants include: the social, economic, and cultural issues related to making the right food choices; purchasing and eating the 'correct' types of food in 'appropriate' quantities; as well as the daily human activity and behaviour related to food. Just as the acquisition of the knowledge of microbiology influenced our understanding of infectious diseases which in turn led to preventive measures for the population, so the historical advances in nutrition have led to a more coherent understanding of the patterns of and the prevention of diet-related diseases of public health importance.

Environmental determinants of variations in disease rates include food and nutrition as one of the primary determinants. In the developing world, numerous nutrient deficiency diseases persist and now coexist with the increasing incidence of diet-related chronic diseases. Developing societies now bear the 'double burden' of malnutrition with the emergence of the so-called 'diseases of affluence' amidst persisting undernutrition in their populations. Changes in the rates and patterns of nutritional disease and their contribution to premature death within a population depend largely on the environmental factors, which include changes in social and economic conditions, the implementation of immunization programmes, improvements in women's social and educational status within the society, and changes in agriculture and food systems and in the availability of food. These changes have been influenced in recent times by globalization and the increasing global trade and the remarkable advances and changes in agricultural practices and the food systems that affect individual diets and lifestyles. National policies that seek to promote economic activity and international trade to boost foreign exchange earnings ignore the impact of these measures on the health of the populations. Economic development is normally accompanied by improvements in the quantity and quality of a nation's food supply and improvements in the immediate environment and living standards of the community. Beneficial environmental influences operate through changes in the provision of and access to hygienic and nutritious food; the availability of potable water, clean housing, and sanitary surroundings; and lack of exposure to environmental toxins. These changes contribute to a food and nutrition-mediated improvement in the body's resistance to infections and better health. The mutual interdependence of the immune and nutritional status of the population probably explains at least some of the gains in public health in Britain in the last century (McKeown 1976).

The quantitative and qualitative changes in our food patterns that lead to such dramatic changes in life expectancy also result in the problems of diet-related chronic diseases. Diet-related chronic diseases occur typically in middle and later adult life and can, by increasing the incidence of premature mortality, undermine the gains in life expectancy. More importantly they lead to morbidity and the resultant disability-adjusted life years (DALYs) lost as well as contributing to economic losses and reducing the quality of life. These diet-related chronic diseases are traditionally regarded as manifestations of overconsumption and self-indulgence in an affluent society. In practice, some of these chronic diseases may be compounded by relatively deficient intakes of some nutrients, thus emphasizing the need for a diversified and balanced daily diet for good health.

Nutrition has re-emerged as being fundamental to public health. Nutritional issues were seen in industrialized, developed societies as relating to deficiency diseases, which were conquered in the early part of the twentieth century while continuing to persist in the relatively poor, developing countries. Now, food and nutrition are recognized as one of the principal environmental determinants of a wide range of diseases of public health importance globally. These diseases reflect the cumulative impact of a variety of pathophysiological processes over a lifetime and the interactions are often seen as reflecting individual genetic susceptibility, but the different disease patterns of groups living on different diets being manifestly a societal reflection of the impact of dietary factors. The display of nutrient-gene interactions is evident, for example, in obesity, alcoholism, cardiovascular disease, type 2 diabetes mellitus, many gastrointestinal disorders, neural tube defects, and the most prevalent cancers. Molecular epidemiology unravels the basis for genetic susceptibility to some of these disorders while the gene inducers or repressors often prove to be of dietary or environmental origin. Societal features, which determine human behaviour and economic well-being as well as climate, tradition, and culture, all affect food consumption patterns and dietary practices. These are features which need to be considered in public health rather than simply the epidemiological or aetiological aspects of diet-related diseases.

This chapter seeks to take a global view of food and nutrition as determinants of public health. This is particularly important because deficiency diseases are widespread in several parts of the world and yet coexist in the same country with chronic diet-related diseases in adults. Vitamin deficiencies, both clinical and subclinical, continue to manifest in poor communities as well as in apparently healthy populations. Threat of hunger and starvation and severe dietary inadequacy resulting in malnutrition

often emerges during conflict and other emergencies. This chapter is structured in such a way that it deals with both sides of the 'mal' nutrition in humans as relevant to public health.

Food and nutrition security

The pre-eminent determinant of 'hunger' (household food insecurity) is poverty in societies. The recognition that poverty and hunger go hand in hand is manifest in the United Nations (UN) Millennium Development Goals (MDGs), which specify targets for the reduction of both global poverty and hunger by the year 2015 (MDG 1). Improving household food security is one of the objectives of all democratic societies and constitutes an important element of the human right to adequate food. *Food security* is defined as 'the access by all people at all times to the food they need for an active and healthy life'. The inclusion of the term 'household' ensures that the dietary needs of all the members of the household are met throughout the year. According to the UN Food and Agricultural Organization (FAO) food insecurity is thus, 'a situation that exists when people lack secure access to sufficient amounts of safe and nutritious food for normal growth and development and an active and healthy life' (FAO 2000). Food insecurity may be caused by the unavailability of food, insufficient purchasing power, inappropriate distribution, or inadequate use of food at the household level. Hence current definitions of food security emphasize the 'availability', 'accessibility', 'stability', and 'utilization' of food.

The achievement of household food security requires an adequate supply of food to all members of the household, ensuring stability of supply all year round, and the access, both physical and economic, which underlines the importance of the entitlement to produce and procure food. Food insecurity may be a result of the unavailability of food, inadequate purchasing power, or inappropriate utilization of food at the household or individual level. Thus, food security at the household level is a complex phenomenon attributable to a range of factors that vary in importance across regions, countries, and social groups, as well as over time (Shetty 2006). It is described in terms of the availability and stability of good quality, safe, and nutritious food supplies, and the access to, and utilization of, this food. All these criteria must be met for the consumption of a healthy diet and the achievement of nutritional well-being.

Availability relates to the adequacy of a varied and nutritious food supply and is influenced principally by factors that promote agricultural production and trade. Factors that influence this include policies and incentives, access to natural resources, and the availability of agricultural inputs, skills, and technologies including biotechnology. Stability of the level and types of foods available for consumption is subject to seasonality and by the sustainability of production and farming systems in practice. These in turn depend on the efficiency of market systems, including pricing mechanisms and infrastructure such as transport and warehousing, which influences the storage, distribution, and flow of food. While reduction of food losses through improvements in food storage and processing also affects stability, the nature of the farming system adopted and its effect on the environment and on sustainability is also a key determinant of the stability of food supplies in the medium to long term.

Access that a community, household, or individual has to food is a reflection of the ability to either grow and retain the food grown

for consumption, to purchase the food from the market, or to acquire it by a combination of strategies that are described as representing 'entitlements' to food (Sen 1981). This system depends on a range of factors such as: access to resources such as land, water, agricultural inputs, and improved technologies; the nature of the food marketing system and the infrastructure to support it; purchasing power and food prices; and consumer perceptions, behaviour, and preferences. Utilization is more concerned with the biological availability of the food after it has been ingested. While age, body size, and physical activity levels are important determinants, the absence of disease and parasitic infestations also influence the utilization of nutrients by the body. As a consequence, the biological utilization of food is largely influenced by environmental factors such as clean water and good sanitation.

The necessity to include nutrition into food security evolved over time as nutrition security in principle is more than food security (Shetty 2009). The nutrition focus adds physiological requirements for different nutrients and the determinants of their bioavailability and bioutilization as well as aspects of caring practices and health services and healthy environments that influence it. *Nutrition security* can be defined as 'adequate nutritional status in terms of protein, energy, vitamins, and minerals for all household members at all times' (Quisumbing et al. 1995, p. 12). While this definition illustrates the consideration of the need for food to ensure optimal supply of nutrients in the diet, i.e. physiological needs, other definitions of nutrition security focus on the vulnerable individual and their needs related to non-food factors. While pointing out the need for a paradigm shift in policy formulation from attention to food security at the aggregate level to nutrition security at the level of each individual, Swaminathan (2008) defines nutrition security as, 'physical, economic and social access to balanced diet, safe drinking water, environmental hygiene, primary health care and primary education'. This definition of nutrition security involves both food and non-food factors and consequently food and nutrition security integrates both conceptual frameworks. The recognition that food, which includes water, is a substance that people eat and drink to achieve an adequate nutritional status, i.e. maintain life and physical, cognitive, and social development, and that it has to meet physiological requirements in terms of quantity, quality, and safety and be socially and culturally acceptable, influenced and amended the definition further. Accordingly, '*food and nutrition security* is achieved, if adequate food (quantity, quality, safety, socio-cultural acceptability) is available and accessible for and satisfactorily utilized by all individuals at all times to achieve good nutrition for a healthy and happy life' (Weingartner 2005, p. 5).

Undernutrition in children and adults

The causes of undernutrition are multidimensional and its determinants include both food- and non-food-related factors such as socioeconomic, cultural, and environmental deprivations. Although establishing a relationship between these variables, and the indicators of undernutrition do not necessarily imply causality, they demonstrate that in addition to food availability many social, cultural, health, and environmental factors influence its prevalence. People faced with inadequacy of food are generally poor, but not all the poor are undernourished. Even in households that are food secure, some members may be undernourished. Income

fluctuations, seasonal disparities in food availability, demand for high levels of physical activity, and proximity and access to marketing facilities may singly or in combination influence the nutritional status of an individual or a household. Transition from subsistence farming to commercial agriculture and cash crops may help improve nutrition in the long run; however, over the short term they may have negative impacts unless accompanied by improvements in access to health services, environmental sanitation, and other social investments. Rapid urbanization and rural to urban migration may lead to nutritional deprivation and alter cultural attitudes in food preferences and practices, and women's time constraints including that available for child-rearing practices, and thus influence the health of the vulnerable in societies. Inadequate housing and over-crowding, poor sanitation, and lack of access to a protected water supply, through links with infectious diseases, are potent environmental factors that influence biological food utilization and nutrition. Inadequate access to food, limited access to healthcare, and clean environments and insufficient access to educational opportunities are in turn determined by the economic and institutional structures as well as the political and ideological superstructures within society. Thus the presence of undernutrition is not only causally related to food insecurity at the household or individual level, but is also determined by other health-related factors such as access to safe water, good sanitation, healthcare, and appropriate care practices and ensuring fair intra-household food distribution.

Poor nutritional status of populations affects physical growth, cognitive development, intelligence, behaviour, and learning abilities of children and adolescents. It impacts on their physical and work performance and has been linked to impaired economic work productivity during adulthood. Inadequate nutrition predisposes them to infections and contributes to the negative downward spiral of malnutrition and infection. Good nutritional status, on the other hand, promotes optimal growth and development of children and adolescents. It contributes to better physiological work performance, enhances adult economic productivity, increases levels of socially desirable activities, and promotes better maternal birth outcomes. Good nutrition of a population manifested in the nutritional status of the individual in the community contributes to an upward positive spiral and reflects the improvement in the resources and human capital of society.

Low birth weight

Intrauterine growth retardation (IUGR) resulting in low birth weights constitutes a major public health problem in developing countries. A World Health Organization (WHO) Technical Report (WHO 1995) recommended that the 10th percentile of a sex-specific, birth weight-for-gestational-age distribution be designated for the classification of small-for-gestational-age (SGA) infants. While it is difficult to establish with certainty whether the reduced birth weight is the result of *in utero* growth restriction; in developing-country populations the high incidence of SGA infants is largely the result of IUGR.

The definition of IUGR is an infant born at term (>37 weeks of gestation) with a low birth weight (<2500 g). The causes of IUGR are multiple and the most important determinant is maternal environment of which nutrition is the most important factor. Poor maternal nutritional status at conception and inadequate maternal nutrition during pregnancy can result in IUGR. Short

maternal stature, low maternal body weight and body mass index at conception, and inadequate weight gain during pregnancy are all associated with IUGR. Thus IUGR is closely related to conditions of poverty and chronic undernutrition of economically disadvantaged mothers.

More than 96 per cent of low-birth-weight (LBW) infants are born in the developing world and over 20 million children are born each year with LBW accounting for 15 per cent of all births—more than double the level in the developed world (UNICEF 2012). The incidence of low birth weight varies across regions, but South Asia has the highest incidence, at 27 per cent (with India at 28 per cent and Pakistan at 32 per cent).

LBWs due to IUGR are associated with increased morbidity and mortality in infancy. It is estimated that term infants weighing less than 2500 g at birth have a four times increased risk of neonatal death as compared to infants weighing between 2500 and 3000 g and ten times higher than those weighing between 3000 and 3500 g. The risk of morbidity and mortality in later infancy is also considerably higher in these LBW infants and is largely due to increased risk of diarrhoeal diseases and respiratory infections. Barker's studies have consistently demonstrated a relationship between LBW and later adult disease and provide an important aetiological role for fetal undernutrition in amplifying the effect of risk factors in later life thereby increasing the risk of developing diabetes, hypertension, dyslipidaemia, cardiovascular disease, and obesity in adult life (Barker 2004).

Childhood undernutrition

The clinical conditions of childhood undernutrition like kwashiorkor and marasmus are severe forms of malnutrition. They are the tip of an iceberg of widespread mild-to-moderate childhood undernutrition within the community that is relevant from a public health perspective.

The determinants of child undernutrition can be considered as operating at three levels of causality: immediate, underlying, and basic. The immediate determinants are dietary intakes and health status which are in turn influenced by three underlying determinants—household food and nutrition insecurity, care for children and their mothers, and the health environment which includes access to safe water, sanitation, and health services. Care encompasses such variables as breastfeeding and proper and timely introduction of complementary feeding, and the education of women—the primary caregiver, their status, their autonomy, and their access to resources. A poor health environment can result in frequent episodes of infection. A vicious cycle may be established and children in poor communities fail to thrive once they have succumbed to an infectious disease and they then languish, responding poorly to therapy and failing to grow even when presented with apparently adequate amounts of food.

Undernutrition in childhood is characterized by growth failure and hence, in children, assessment of growth has been the single most important measurement that best defines their nutritional status. Measures of height and weight are the commonly used indicators of the nutritional status of the child and classification of childhood undernutrition based on height, weight and age continues to be the backbone of nutritional assessment of both populations and individuals (WHO 1995) when compared against international growth reference standards developed by WHO (2006).

Children throughout the world when well fed and free of infection tend to grow at similar rates irrespective of their ethnic or racial origin, and healthy children everywhere can, when fed appropriately, be expected to grow on average along the 50th centile of a reference population's weight and height for age. By expressing both height and weight as standard deviations or Z-scores from the median reference value for the child's age, the normal range will correspond to the 3rd and 97th centile, (i.e. ± 2 SDs or ± 2 Z-scores). By expressing data in this way, it is possible to express the weight and height data for all children across a wide age range in similar Z-score units and thereby produce a readily understandable comparison of the extent of growth retardation at different ages and in different countries.

A deficit in height is referred to as '*stunting*' whereas a deficit in weight-for-height is considered as '*wasting*'. These two measures are subsumed in the designation of a child's failure to grow in terms of weight-for-age when the deficit is termed '*underweight*'. Wasting can occur on a short-term basis in response to illness with anorexia or malabsorption or because the child goes hungry for several weeks. Changes in weight-for-height therefore reflect the impact of short-term changes in nutritional status. Growth in height, however, is much more a cumulative index of long-term health because growth in length or height stops when a child develops an infection and the subsequent growth may be slow during the recovery period. Children normally grow in spurts and intermittently. Energy intake is not a crucial determinant of height and the energy cost of growth and weight gain is only 2–5 per cent of total energy intake once the child is 1 year of age. Impairment of growth in height occurs in many communities at the time of weaning and up to about 2 years of age. Once the children have failed to maintain their proper growth trajectory for stature they tend to remain on the lower centiles and 'track' at this low level for many years.

While the MDGs targeted underweight in children, more recently the emphasis has shifted from underweight to stunting. The damage caused by lack of good nutrition in the first 5 years of life is largely irreversible and stunted children achieve less in school, are paid less when they enter the workforce, and are at greater risk of becoming overweight and developing chronic diseases later in life. There is now a better appreciation of the crucial importance of nutrition during the critical 1000-day period covering pregnancy and the first 2 years of a child's life, that stunting reflects deficiencies during this period and that health and nutrition interventions need to focus on this crucial period.

Global estimates of the main forms of child undernutrition are summarized in Table 2.7.1. Comparisons from earlier estimates indicate that the prevalence of underweight and stunting remain high despite substantial progress (Black et al. 2013). In most parts of Africa the numbers of underweight and stunting increased during this period while the dramatic progress in Asia is outweighed by the persisting high prevalence and numbers of children affected. Stunting is a serious problem reflecting poor nutrition and frequent infections during the early growth period. Stunting in South Asia seems also to be related to the high incidence in LBW in this region.

Underweight in children is being used as an indicator for monitoring progress towards the MDGs. Overall current analyses demonstrate some progress in reducing child undernutrition—but progress is uneven and in some countries has even deteriorated.

Table 2.7.1 Current estimates and progress since 1990 in the prevalence and numbers of child undernutrition globally and in developing countries of Africa, Asia, and Latin America

	Underweight		Stunting	
	1990	2011	1990	2011
Global				
Prevalence (%)	26.5	15.7	33.5	25.7
Numbers ($\times 10^6$)	163.4	100.7	206.5	164.8
Africa				
Prevalence (%)	23.6	17.7	36.9	35.6
Numbers ($\times 10^6$)	25.3	27.9	39.6	56.3
Asia				
Prevalence (%)	35.1	19.3	41.1	26.8
Numbers ($\times 10^6$)	131.9	69.1	154.6	95.8
Latin America				
Prevalence (%)	8.7	3.4	18.3	13.4
Numbers ($\times 10^6$)	4.8	1.8	10.0	7.1

Prevalence expressed as percentage below -2 SD of WHO International reference value.

Global estimates are predominantly developing countries in the three regions. Latin America includes the Caribbean.

Source: data from *The Lancet*, Volume 382, Issue 9890, Black RE et al., Maternal and child undernutrition and overweight in low-income and middle-income countries, pp. 427–451, Copyright © 2013 Elsevier Ltd. All rights reserved.

To achieve the MDGs more concerted effort is needed, especially in those regions with stagnating or increasing trends in child undernutrition. Well-nourished children have a better chance of surviving and growing into healthy adults. Improving child nutrition requires attention to all three components, i.e. access to adequate and safe food, freedom from illness, and appropriate care. Ensuring optimal child health and growth can contribute to a healthy adult population and accelerate economic growth of countries.

Adult undernutrition

Undernutrition among adults has been neglected and this may have profound significance for the economic growth of developing countries. One simple measure of adult nutritional status is the *body mass index* (BMI), (i.e. body weight in kilograms divided by the square of the height in metres); the most suitable index for both under- and overnutrition in adults (Shetty and James 1994). Adults with a BMI less than 18.5 are considered chronically undernourished while those with a BMI greater than 25.0 or greater than 30.0 are overweight or obese respectively (WHO 2000); the same BMI cut-offs apply to both males and females. Undernourished adults show impairment of physical well-being and exercise capacity and susceptibility to illness and the ability to sustain economic productivity. Hence, it is important to examine adult undernutrition.

Anthropometric measures of adult undernutrition provide objective estimates of the prevalence of undernutrition worldwide. In practice, children and adults may adapt to a shortage of food by reducing their physical activity without changing their body

weight. Thus, measures of the prevalence of low weight-for-height provide only a limited index of food insecurity as physical activity is fundamental and desirable for physiological well-being and for limiting the development of chronic disease while promoting societies to prosper through physically demanding economic activity.

For many years the FAO has attempted to assess the global prevalence of food insecurity by relating complex measures of food supply and its variable distribution between households with estimates of the population's energy needs. The numbers of undernourished estimated most recently by FAO are 870 million of which 850 million are in developing countries (FAO 2012). Since reducing by half the proportion of the food insecure by 2015 is one of the targets set in MDG 1, monitoring progress is essential. While there has been progress in this direction since the 1990s, most of the progress has been achieved before 2007/2008, and since then progress has stalled. While the prospect of meeting the MDG 1 target is good, progress has been variable with some regions showing a worsening of the situation. Reliable global estimates of adult undernutrition based on BMI are not available since nutritional surveys rarely include adult men and the issue of adult undernutrition has also largely been ignored. With awareness of the increasing problem of overweight and obesity, more information based on anthropometric surveys of adults is being generated which will provide global data on adult undernutrition.

The basic causes of undernutrition are clearly political and socioeconomic. Agricultural revolutions such as the green revolution have increased food availability and helped meet the food needs of the population. Agricultural productivity has increased worldwide and developing countries are increasingly producing more food even when expressed on a per capita basis. Food prices for most commodities, particularly for cereals, had also fallen to their lowest until the food price crisis in 2007/2008. However, poverty is often the basis of a failure to have access to food even when food is available in plenty; and is aggravated by the rise in food prices. Accelerated food production will alleviate hunger only to the extent that the resources used in the process reduce poverty more than they would if used in other ways. Thus food entitlement decline is a more important force in sustaining poverty and undernutrition than a decline in the availability of food in developing societies.

Micronutrient malnutrition

Micronutrient malnutrition, also referred to as 'hidden hunger', is caused by lack of adequate micronutrients (vitamins and minerals) in the habitual diet. Diets deficient in micronutrients are characterized by high intakes of staple food and cereal crops, but low consumption of foods rich in bioavailable micronutrients such as fruits, vegetables, and animal and marine products, i.e. the lack of a diversified diet. Micronutrient deficiencies are important from a public health perspective as they affect several billion people worldwide (Table 2.7.2) and can impair cognitive development and lower resistance to disease in children and adults. They increase the risk to both mothers and infants during childbirth and impair the physical ability and economic productivity of men. The costs of these deficiencies in terms of lives lost and reduced quality of life are enormous, not to mention the economic costs to society.

Strategies to combat micronutrient deficiencies in communities have included: (1) *supplementation* of specific nutrients to meet

Table 2.7.2 Estimated global impact of micronutrient malnutrition

Micronutrient malnutrition	Estimated impact
Vitamin A deficiency	140 million preschool children affected with VAD ¹ Contributes to 1.15 million deaths in children every year ² 4.4 million children suffer from xerophthalmia ¹ 6.2 million women suffer from xerophthalmia ¹
Iron deficiency	2.0 billion women (96 million of them pregnant) ² 67,500 maternal deaths per year from severe anaemia ²
Iodine deficiency	1.98 billion at risk with insufficient or low iodine intakes ³ 15.8% of population worldwide have goitre ³ 17.6 million infants born mentally impaired every year ²
Folate deficiency	Responsible for 200,000 severe birth defects every year ²

the immediate deficits; (2) *fortification* of staple food items in the daily diet—another successful strategy that has been adopted to deal with specific nutrient deficiencies like iodine; (3) *food-based approaches* which include promoting kitchen gardens to enable families to produce and consume a diversified diet and improve the nutrition of households—promoted to reduce vitamin A deficiency in developing countries; (4) a potential strategy that is showing signs of great promise is to improve the nutrient quality of commonly consumed staples by agricultural biotechnology—a process referred to as *biofortification*. The micronutrient deficiencies that will be addressed in this chapter include only the significant ones from a public health viewpoint.

Iron deficiency and anaemia

Iron deficiency is probably the most common nutritional deficiency disorder in the world and it is estimated that globally about 1.62 billion people suffer from anaemia (de Benoist et al. 2008). Hence anaemia and iron deficiency are major public health problems with adverse consequences especially for women of reproductive age and for young children. The predominant cause of iron deficiency is nutritional, the diet failing to provide for the body's requirements of iron. Intestinal helminthic infestations exacerbate iron deficiency by loss of blood from the gut and malaria also contributes to anaemia in tropical countries. A low intake of iron and/or its poor absorption then fails to meet the enhanced demands for iron and anaemia results. Low intakes of folic acid and vitamin B₁₂ also contribute to anaemia.

The consequences of iron deficiency are numerous as iron plays a central role in the transport of oxygen in the body and is also essential in many enzyme systems. Iron deficiency leads to changes in behaviour, such as attention, memory, and learning in infants and children, and negatively influences the normal defence systems against infection. T-lymphocyte function, phagocytosis, and the killing of bacteria by neutrophilic leucocytes are affected. In pregnant women, iron deficiency contributes to maternal morbidity and mortality, and increases risk of fetal morbidity,

mortality, and LBWs (Viteri 1997). Iron deficiency results in a reduction in physical working capacity and productivity of adults both in agricultural and industrial work situations. These functional impairments are economically important as it is estimated that median value of productivity losses is about 0.9 per cent gross domestic product (GDP) and the economic impact of iron deficiency can vary from 2 per cent GDP in the case of Honduras to 7.9 per cent in Bangladesh (Horton and Ross 2003).

Iron deficiency disorders encompass a range of body iron depletion states. The least severe is *diminished iron stores* diagnosed by decreased serum ferritin levels and not usually associated with adverse physiological consequences. The intermediate, *iron deficiency without anaemia* on the other hand, is severe enough to affect production of haemoglobin without haemoglobin levels falling below clinical criteria indicative of anaemia and characterized by decreased transferrin saturation levels and increased erythrocyte protoporphyrin. The severe form with clinical manifestation is *iron deficiency anaemia* (IDA).

IDA is a serious problem worldwide and the dominant cause in all cases is nutritional iron deficiency (Table 2.7.3). The highest prevalence figures for IDA are seen in developing countries. Global estimates are 18.1 per cent for children under 5 years and 19.2 per cent among pregnant women (Black et al. 2013). Even in developed countries the prevalence of IDA is significant. Based on the estimates of IDA as a risk factor for mortality, the total attributed global burden is estimated at 841,000 deaths and over 35 million DALYs (Stoltzfus et al. 2004).

In Africa, Asia, and South America, the availability of iron in diets has been deteriorating and IDA continues to be a serious public health problem. The availability of iron in the diet for absorption is affected by both the form of iron and the nature of foods concurrently ingested. Iron exists in the diet in two forms: (1) as 'haem iron', found only in animal source foods, readily absorbable and not influenced by other dietary constituents; and (2) as 'inorganic iron', not readily available and strongly influenced by foods ingested at the same time. Both animal foods and ascorbic acid promote the absorption of inorganic iron. Diets which are primarily cereal- and legume-based may contain much iron but, in the absence of co-factors such as ascorbic acid or presence of phytates,

they provide only low levels of bioavailable iron. Concern about iron deficiency is an important reason for recommending the consumption of some animal source foods as well as foods with ascorbic acid for populations who rely predominantly on a cereal-based diet.

The strategies to combat iron deficiency include: (1) *iron supplementation*; (2) *iron fortification* of certain foods; (3) *dietary modification* to improve the bioavailability of dietary iron by modifying the composition of meals; and (4) *parasitic disease control*. Iron and folate supplementation for pregnant women are currently widely implemented in several countries; and many countries have a universal preventive supplementation programme during pregnancy. Iron supplementation of preschool- or school-aged children is also carried out in several countries. Fortification of foods with iron is a preventive measure for improving and sustaining adequate iron nutrition over a longer term. Many countries like Canada and the United States have fortified foods with iron and studies in developing countries have demonstrated the effectiveness of iron fortification of foods and salt provided these programmes are based on careful planning and follow well-established guidelines (Viteri 1997). Improvement in the supply, consumption, and the bioavailability of iron in food is an important strategy to improve iron status of populations. Food-based approaches such as diversification and modification of the diet and the inclusion of animal source foods have been tried successfully to improve iron intakes. The bioavailability of iron is influenced by the composition of the meal and food preparation methods. The consumption of ascorbate-rich foods enhances iron absorption while limiting the content of phytate will improve iron bioavailability. All of these barriers can be addressed by diversification and modification of the diets at the household or community level. Sustainable and successful strategies include the promotion of homestead gardening, small livestock production, and investment in community level technologies for preservation and storage of seasonal fruits and vegetables that are rich in micronutrients like iron (Thompson and Amoroso 2011). The introduction of biofortified cereal crops with higher content of minerals like iron and zinc is also undergoing trials to address this huge public health problem.

Table 2.7.3 Numbers of people (in millions) affected with iron deficiency anaemia based on blood haemoglobin concentration in different regions of the world

	Children		Women (15–49 years)		Men (15–59 years)	Elderly
	Preschool (millions)	School age (millions)	Pregnant (millions)	Non-pregnant (millions)	(millions)	(millions)
Global	293.1	305	56.4	468.4	260	164
Africa	83.5		17.2	69.9		
Americas	23.1		3.9	39.0		
South East Asia	115.3		18.1	182.0		
Europe	11.1		2.6	40.8		
East Mediterranean	0.8		7.1	39.8		
Western Pacific	27.4		7.6	97.0

Malaria and intestinal parasites are important contributors to IDA in endemic areas. In populations where hookworm is prevalent, effective treatment of this infection has reduced IDA in school-age children (Stoltzfus et al. 1997). Thus strategies that address iron nutrition whether food based, or by supplementation or fortification, must be integrated with programmes such as malaria prophylaxis, helminth control, environmental health, and control of other micronutrient deficiencies to maximize effectiveness (WHO/UNICEF/UNU 2001).

Iodine deficiency disorders

The term ‘iodine deficiency disorder’ (IDD) refers to a complex of effects arising from deficient intakes of iodine. The mountainous areas of the world are likely to be iodine deficient because rain leaches iodine from the rocks and soils. Severely deficient areas are the Himalayas, the Andes, the European Alps, and the vast mountainous regions of China. It also occurs in flooded river valleys of Eastern India, Bangladesh, and Burma. The Great Lake basins of North America are also iodine deficient. Excessive intakes of goitrogens in food (excessive consumption of *cassava* or *brassica* group of vegetables) and water, as well as the deficiency of certain trace elements in the soil or food chain (e.g. selenium) may interfere with iodine uptake and metabolism and can cause or amplify the effects of iodine deficiency.

The prevalence of manifest IDD in the form of goitre varies globally and at present is confined to developing countries, largely because public health initiatives such as mandated or permitted iodization of salt have been in force in the developed world. Iodine deficiency and goitre is still prevalent in Central and Eastern Europe. According to recent estimates, goitre prevalence in developing countries is 15.8 per cent (WHO 2004). However, this figure masks the enormous numbers who are at risk of IDD based on urinary iodine status that reflects the insufficiency of iodine intake in the diet (Table 2.7.4). Iodine deficiency is also responsible for over 200,000 severe birth defects worldwide while also contributing to lower the intellectual capacity by as much as 10–15 percentage points (UNICEF and Micronutrient Initiative 2004).

IDD in humans is due to deficiency of iodine in the diet. Both water and foods are sources of iodine with marine fish being the richest source of iodine. Milk and meat are rich sources of iodine and fruits, legumes, vegetables, and freshwater fish are also important sources. Goitrogens in the diet are of secondary importance as aetiological factors in IDD. It has been shown that staple foods consumed largely by poor rural populations, such as cassava, maize, sweet potatoes, and lima beans contain cyanogenic glucosides which release a goitrogen thiocyanate. Cassava is now implicated as an important contributor to the endemic goitre and cretinism in non-mountainous Zaire and in Sarawak in Malaysia. Selenium deficiency in the soil can result in manifestations of IDD in the presence of modest iodine deficiency and is considered relevant in several regions of China.

Iodine is readily absorbed from the diet and is essential for the synthesis of thyroid hormones which are essential for normal growth and development. Failure to synthesize sufficient triiodothyronine as a result of iodine deficiency may be a factor in the stillbirths that occur as a part of the spectrum of IDD. Thyroid hormone deficiency leads to severe retardation of growth and maturation of all organs and the brain is particularly susceptible to damage during the fetal and early postnatal periods. The

Table 2.7.4 Proportion of population and number of individuals with insufficient iodine intake in school-age children (6–12 years) and the general population and total goitre prevalence in the same UN regions

UN region	Insufficient iodine intake (urinary iodine <100 micrograms/L)		Total goitre prevalence
	School-age children	General population	
Africa	42.7% (59.7 millions)	43.0% (324.2 millions)	26.8%
Asia	38.3% (187.0 millions)	35.6% (1239.3 millions)	14.5%
Europe	53.1% (26.7 millions)	52.7% (330.8 millions)	16.3%
Latin America and The Caribbean	10.3% (7.1 million)	10.0% (47.4 millions)	4.7%
North America	9.5% (2.1 millions)	64.5% (19.2 millions)	—
Oceania	59.4% (2.1 million)	64.5% (19.2 million)	12.9%
Total	36.5% (285.4 millions)	35.2% (1988.7 millions)	15.8%

Figures in parentheses are numbers of individuals at risk estimated from UN Population estimates for 2002.

spectrum of IDDs in humans, from the fetus to the adult, has been outlined by Hetzel (1987).

The public health initiatives for correcting iodine deficiency include the following: *iodization* of salt has been the most favoured method and has greatly reduced the prevalence of IDDs in Switzerland, the United States, and New Zealand. Since its first successful introduction in the 1920s in Switzerland (Bürgi et al. 1990) successful programmes have been reported in Central and South America, in Europe, and in Asia. However, several developing countries have encountered problems with salt iodization programmes because it is difficult to produce and maintain enough high-quality iodized salt for large populations such as in India and Bangladesh. The costs of iodized salt and its availability and distribution to remote regions can also be a problem and may be compounded by cultural prejudices about the use of iodized salt and the loss of iodine with cooking if salt is not added after cooking. *Iodized oil* injections have been used to prevent goitre and cretinism in New Guinea (Pharoah and Connolly 1987). Iodized oil is suitable for mass programmes and can be carried out alongside mass immunization programmes. These methods have been successful in China, Indonesia, and Nepal. The major problems with iodized oil are the cost, the initial discomfort, and the likely potential risk of the transmission of hepatitis B and HIV. The need for trained personnel to inject iodized oil can be a further disadvantage. Iodized oil by mouth may be an alternative and oral iodized oil has been shown to be as effective in a single oral dose as an intramuscular injection (Phillips et al. 1988).

Although the effects of oral iodized oil seem to last for only half as long as a similar dose of injected iodized oil, oral iodized oil does not suffer from the disadvantages of iodized oil injections and so is a preferred method for use in remote areas. IDD's are excellent examples of nutritional deficiency disorders of public health importance which can readily be addressed if mass community programmes are undertaken.

Zinc deficiency

Zinc deficiency is the result of inadequate intake or absorption of zinc from the diet. Excess losses of zinc during episodes of diarrhoea also contribute to deficiency. The composition of the diet can influence zinc bioavailability as high levels of phytates in the diet may result in poor absorption while animal source foods increase availability. Based on inadequate intakes in the diet it has been estimated that globally 31.3 per cent of the population have inadequacy of zinc in the diet (Caulfield and Black 2004) while zinc deficiency has been estimated globally at 17.3 per cent (Black et al. 2013).

Worldwide, zinc deficiency is responsible for approximately 16 per cent of lower respiratory tract infections, 18 per cent of malaria, and 10 per cent of diarrhoeal disease and 1.4 per cent (0.8 million) of deaths worldwide. Attributable DALYs were higher, with zinc deficiency accounting for about 2.9 per cent of worldwide loss of healthy life years. Dietary diversification and the addition of animal source foods in the diet have helped reduce zinc deficiency and agricultural technologies such as addition of zinc enriched fertilizer to the soil (Gibson et al. 2007) and the use of biofortified crops with higher zinc and iron content have also been successfully tried to reduce the burden of zinc deficiency as a public health problem.

Vitamin A deficiency

Vitamin A deficiency (VAD) is a major public health problem in many developing countries. VAD leads to night blindness and xerosis of the conjunctiva and cornea and disrupts the integrity of their surface and causes corneal clouding and ulceration and may lead to blindness in children. Xerophthalmia continues to be a major cause of childhood blindness despite the intensive prevention programmes worldwide. The parts of the world most seriously affected include South and South East Asia, and many countries in Africa, Central America, and the Near East. Extrapolations from the best available data suggest that 140 million preschool children and more than 7 million pregnant women suffer from VAD every year (Standing Committee on Nutrition 2004). This report also states that another 4.4 million children and 6.2 million women suffer from xerophthalmia. Nearly half the cases of VAD and xerophthalmia occur in South and South East Asia.

VAD manifests as night blindness and it is estimated that globally 5.17 million preschool age children and 9.75 million pregnant women suffer from night blindness—the highest prevalence in pregnant women in Africa and South and South East Asia (WHO 2009). Global estimates are 0.9 per cent for preschool children and 7.8 per cent for pregnant women (Black et al. 2013). Based on low serum retinol levels the estimates globally are much higher at 190 million preschool children and 19.1 million pregnant women with Africa and South and South East Asia having the highest prevalence. Global estimates are 33.3 per cent for preschoolers and 15.3 per cent for pregnant women (Black et al. 2013). About

20–40 million suffer from subclinical deficiency of vitamin A which has serious consequences for child survival since VAD decreases resistance to infections and increases risk of mortality and estimates suggest this to be between 1.2 to 3.0 million children. VAD may also be associated with increased maternal morbidity and mortality.

Vitamin A belongs to a class of compounds called retinoids. Pro-vitamin A carotenoids, chiefly β -carotene, is also included. Preformed vitamin A is chiefly found in dairy products, egg yolk, in some fatty fish, and in the livers of farm animals and fish. Carotenes are generally abundant in yellow fruits (papayas, mangoes, apricots, peaches) and vegetables (carrots). Absorption of vitamin A is about 80 per cent complete in the presence of an adequate fat intake, while the absorption of carotenoids is highly bile salt dependent. Vitamin A (retinol and retinoic acid) plays a very important role in the body in cellular development and differentiation. Retinol also has a vital role in normal vision, particularly by the rods in the retina. Thus, one of the earliest manifestations of VAD is night blindness.

There is now increasing evidence that vitamin A supplements in deficient populations can reduce morbidity, mortality, and blindness although there is emerging evidence that this is not always the case (Awasti et al. 2013). Xerophthalmia has become less prevalent in hyperendemic areas in recent years and intervention strategies with periodic megadose vitamin A supplementation may have contributed to this. It is now the practice to provide vitamin supplements with immunization programmes in many countries with the aim of providing at least one dose of vitamin A per year for all children aged 6 months to 5 years. The fortification of dietary items which are universally consumed, e.g. sugar in Central America (Arroyave et al. 1981) and monosodium glutamate in Indonesia (Muhilal et al. 1988), have also had a favourable impact on the vitamin A status of the population. Triple fortification (iodine, iron, and vitamin A) of salt using microcapsules has been shown to be effective (Zimmerman et al. 2004). Following on the success of sugar fortification in Central America it has been successfully tried in Zambia and South Africa and the Philippines have successfully implemented fortification of cereals (wheat and maize flour) with vitamin A (UNICEF and Micronutrient Initiative 2004).

The problems with food fortification are essentially logistical and technological and many developing countries are beginning the process of fortifying staple foods and condiments, including margarine, cooking oil, and soya sauce, with vitamins (and minerals). Food intakes from different regions of the world show limited vitamin A availability, and the problem is exacerbated by withholding vegetables and fruits from children and pregnant and lactating women for cultural reasons in some parts of the world. Nutrition education is the only approach when VAD develops despite fruit and vegetable sources of the vitamin being in plentiful supply. These foods are not incorporated into the diets of young children and mothers, due either to lack of knowledge or cultural biases. Nutrition education together with practical advice and help with growing cheap, nutritious vegetables in home kitchen gardens may help eradicate VAD. Horticultural approaches are effective and potentially sustainable in improving vitamin A status and micronutrient status generally. Economic development and poverty reduction programmes are likely to improve socioeconomic status and may indirectly contribute to reducing the problem of VAD.

Folate deficiency

Folate enables cell division and tissue growth. Adequate folate in the diet helps prevent malformations that affect the neural tube and spinal cord such as anencephaly and spina bifida as well as birth defects like cleft lip and palate. Without adequate folate in the diet, two in every 1000 pregnancies may end up with a serious birth defect. Folate deficiency is also associated with increased risk of preterm delivery and LBW (Scholl and Johnson 2000) and may also contribute to anaemia, especially in pregnant and lactating mothers (Dugdale 2001). It may thus contribute indirectly to increased maternal illness and mortality. With the increasing awareness of the role of folate in reducing the risk of heart disease and stroke, a case is being made for folate fortification of flour, a strategy already adopted in the United States and Canada.

Addressing the challenge of micronutrient malnutrition

It is important to acknowledge the contribution of several non-government organizations (NGOs), many of them specialized in addressing specific micronutrient deficiencies (e.g. International Council for the Control of Iodine Deficiency Disorders (ICCID) with the objective of the sustainable elimination of IDD) while many others such as Micronutrient Initiative tackle all major micronutrient deficiencies of public health significance and the important role they play in addressing the problem of 'hidden hunger' worldwide. They closely work in partnership with governments, aid agencies, and with the UN agencies and the community to further this laudable objective.

This section has hitherto dealt with only some of the more important nutritionally determined deficiency disorders of public health importance. It is important to know that segments of populations in the world suffer from other nutritional disorders such as the deficiency of fluoride, zinc, selenium, B group vitamins, and ascorbic acid. Some of these seem to occur during seasonal deficiencies in their availability and accompany famine and conflict situations when they are seen in refugee camps. In all regions of the world there are still populations affected by one or more of these deficiencies despite the significant advances that have been made in controlling nutritional deficiency disorders. In some regions of the world, largely the result of increasing population size, the numbers of undernourished are increasing even if the population prevalence is declining. In many there is a shift in the severity of the deficiency diseases with decreasing numbers with severe deficiency and increasing numbers with mild-to-moderate deficiencies. For a majority of these countries there is still the need to pursue vigorous policies and targeted action to combat the various nutritional deficiency disorders as a part of the comprehensive health-oriented national food and nutrition policies.

Consequences of undernutrition and micronutrient deficiencies

An issue that deserves attention is to ask the question: humanitarian considerations apart, does widespread undernutrition and micronutrient malnutrition matter? And is there a case for investing in better nutrition? According to UNICEF, approximately half the economic growth achieved by developed countries of Western Europe since 1790 until 1980 can be attributed to better nutrition

and improved health and sanitation (UNICEF 1997). The social and economic costs, apart from costs to the individual due to poor nutrition, are huge. Improving nutrition of communities reduces healthcare costs. More than half of child mortality in developing countries is attributable to underweight and the increased risk of infectious diseases. Underweight is the leading risk factor in the global burden of disease, and among developing countries with high mortality it contributes to nearly 15 per cent of the attributable DALYs (WHO 2002). Preventing LBW and stunting also reduces childhood mortality and morbidity. The intimate links between undernutrition in early life, including LBW and the increasing risk of chronic disease in later adult life, are well established. Diagnosis and treatment of chronic diseases like heart disease, diabetes, and cancer are expensive and will distort the limited public health budgets of developing countries.

Undernourished children become smaller adults and demonstrate lower physiological performance and reduced physical and work capacity. Employment prospects and productivity of short-statured and undernourished individuals are impaired (Spurr 1987). It shortens productive lives and increases absence due to illness; impacting in turn on economic productivity of countries. Micronutrient deficiencies such as iron deficiency impair physical capacity and work productivity and contribute to economic losses.

Poor nutrition impairs cognitive development and learning in undernourished children in developing societies. Grantham-McGregor (1995) has demonstrated that children who are stunted and live in deprived circumstances have major deficits in intellectual and cognitive development and social behaviour. Children's scholastic ability in their teens can be strongly influenced by interventions in the second and third year of life. Iodine deficiency and the syndrome of cretinism is another example of the role of nutrition in brain development and function. Even postnatal iodine deficiency can lead to slowing of mental processing that results in permanent impairment of mental development because of the need for adequate nutrition during critical periods of brain development. Similarly, Pollitt (1991a, 1991b) has demonstrated that iron deficiency anaemia can permanently handicap children at a crucial time in their development even though iron deficiency per se is not enough to produce demonstrable clinical deficiency. Grantham-McGregor's (1995) studies show that food that stimulates longitudinal bone growth also stimulates brain development, thus implying a more generic demand for a range of nutrients if mental function is to improve. All of these have significant relevance to the fact that children's education is the cornerstone to social and economic development of nations and is now an important component of the MDGs (MDG 2). The benefits of sustained mental and physical development from childhood into adult life ensure that healthy adults with the physical capacity to maintain high work outputs and with the intellectual ability to flexibly adapt to new technologies in this rapidly globalizing world will be a national asset. The importance of food and nutrition in the development of human capital in developing societies can never be underestimated.

Strategies to address the problem of undernutrition in developing societies

Reduction of poverty and hunger are high up among MDGs since achieving MDG 1—halving poverty and hunger by 2015—is central

to achieving the other health-related MDGs. Economic growth and development should reduce the burden of undernutrition, but the reduction is slow and many people continue to suffer needlessly. There is thus a need for well-conceived policies for sustainable economic growth and social development that will benefit the poor and the undernourished. Given the complexity of factors that determine malnutrition of all forms, it is important that appropriate food and agricultural policies are developed to ensure household food security and that nutritional objectives are incorporated into development policies and programmes at national and local levels in developing countries. The deleterious consequences of rapid growth and development need to be guarded against and policies need to be in place to prevent one problem of malnutrition replacing another in these societies.

The pre-eminent determinant of household food insecurity is poverty in societies. Several policy measures undertaken by governments in developing countries are aimed at ensuring food supply and household food security. Good governance and democracy and well-targeted aid and the implementation of policies and relevant programmes will reduce the burden of hunger and undernutrition in developing countries. The adoption of the MDGs by the world's leaders at the Millennium Summit of the UN and the declaration to 'free all men, women, and children from the abject and dehumanizing conditions of extreme poverty' contributed a sense of urgency to address issues of nutrition and public health. Several programmes to address the problem of nutrition worldwide have been initiated; significant among them has been the Scaling Up Nutrition (or SUN) Initiative. The SUN movement is built through the engagement of nations affected by undernutrition and is a country-led movement that brings organizations together across sectors to support national plans to scale up nutrition and focuses attention on the 1000-day window of opportunity for impact. The SUN movement promotes the implementation of evidence-based nutrition interventions, as well as integrating nutrition goals into broader efforts in critical sectors such as health, social protection, development, and agriculture. The latter has resulted in the recent focus on agricultural strategies to sustainably reduce undernutrition just as this approach in the past addressed the challenge of food insecurity.

Diet, nutrition, and chronic non-communicable diseases

The evidence relating food and nutrition to chronic non-communicable diseases (NCDs) such as cardiovascular disease, type 2 diabetes mellitus, and cancers comes from population-based epidemiological investigations and trials. Descriptive population-based epidemiological investigations yield valuable data that lead to important hypotheses, but cannot be used alone to establish the causal links between diet and disease. The most consistent correlation between diet and chronic diseases has emerged from comparisons of populations or segments of population with substantially different dietary habits. Epidemiological studies, such as cohort studies and case-control studies, that compare information from groups of individuals within a population usually provide more accurate estimates of associations. Examining population-based epidemiological data relating diet to disease recognizes that every population consists of individuals who vary in their susceptibility to each disease and

part of this difference in susceptibility is genetic. As the diet within a population changes in the direction that measures the risk of the specific disease, an increasing proportion of individuals, particularly those most susceptible to the risk, develop the disease. As a result of this interindividual variability in the interaction of diet with an individual's genetic make-up and the individual's susceptibility to disease, some diet-disease relationships are difficult to identify within a single population. In experimental clinical studies and randomized and controlled trials, long exposures may be required for the effect of diet as a risk factor to be manifest. Strict inclusion criteria for participants need to be adhered to, to show the effect with small numbers in a reasonable length of time. These in turn may restrict the study to homogenous samples and thus limit the applicability of results to the population at large. Despite these limitations, when carefully designed studies show consistent findings of an association between specific dietary factors and a chronic disease, they generally indicate a cause and effect relationship.

Diet and cardiovascular diseases

The commonest cardiovascular diseases that are diet-related are coronary heart disease (CHD) and hypertension.

Coronary heart disease

CHD emerged as a burgeoning public health problem in Europe and North America after the Second World War and by the end of the 1950s had become the single major cause of adult death. The rates of CHD showed marked international differences with overall rates being higher among men than women. Mortality rates were sevenfold higher in some Eastern European countries while threefold differences were evident between Scotland and Spain or Portugal. Migration can contribute to either an increase, as in the case of Japanese moving to the United States, or decrease when Finns move to Sweden—migrants tending to approach the rates in their host countries. In the case of migrants from South Asia to the United Kingdom, however, the rates exceed the hosts implying some genetic susceptibility increasing risk in the host environment. The nearly fivefold difference in CHD rates among different countries and the intrapopulation variations in rates, by socioeconomic class, ethnicity, and geographical location, have revealed the dietary basis of CHD. The marked changes in CHD rates in migrant populations that moved across a geographical gradient in CHD risk provided evidence of the environmental nature of the causative factor.

Several prospective population studies have documented the relationship between habitual diets and the risk of CHD. These longitudinal studies have shown that several foods in the diet like wholegrain cereals, fish, fruits and vegetables, nuts, and moderate intakes of red wine are protective and reduce risk of CHD while others such as dietary saturated fat, trans fatty acids, and increased consumption of coffee may increase the risk of CHD. On the basis of the evidence, the WHO Expert Committee on Prevention of CHD (WHO 1982) concluded that the relationship of lipids in the diet and blood met the criteria for an epidemiological association to be termed causal. These data were backed by other evidence from intervention trials and animal experiments demonstrating the effects of diet on coronary artery atherosclerosis.

This relationship between dietary factors and CHD was supported by the results of the Seven Country Study (Keys 1980). The

saturated fat intake varied between 3 per cent total energy in Japan and 22 per cent in Finland while the 15-year CHD incidence rates varied between 144 per 10,000 in Japan and 1202 per 10,000 in Finland. The annual incidence of CHD among 40–59-year-old men initially free of CHD was 15 per 100,000 in Japan and 198 per 100,000 in Finland. Evidence from 16 well-defined cohorts in seven countries and its correlation to the 10-year incidence rate of CHD deaths provided further support for this causal association. The strongest correlation was noted between CHD and percentage of energy derived from saturated fat, while total fat was not significantly correlated with CHD.

In the Seven Country Study, the *serum total cholesterol* values were 165 mg/dL in Japan and 270 mg/dL in Finland, and the variation in serum total cholesterol levels between populations could largely be explained by differences in saturated fat intake. The risk of CHD seemed to rise progressively within the same population with increases in plasma total cholesterol. Observational studies suggest that one population with an average total cholesterol level 10 per cent lower than another will have one-third less CHD and a 30 per cent difference in total cholesterol predicts a fourfold difference in CHD (WHO 1990). The Seven Country Study showed a strong positive relationship between saturated fat intake and total cholesterol level; populations with an average saturated fat intake between 3 per cent and 10 per cent of the energy intake were characterized by serum total cholesterol levels below 200 mg/dL and by low mortality rates from CHD. As saturated fat intakes increased to greater than 10 per cent of energy intake a marked and progressive increase in CHD mortality was noticed. Saturated fats raise total and *low-density lipoprotein* (LDL) cholesterol; and of these fatty acids myristic and palmitic acids abundant in diets rich in dairy and meat products have the greatest effects (Table 2.7.5).

Several prospective studies have shown an inverse relation between *high-density lipoprotein* (HDL) cholesterol and CHD incidence. However, HDL cholesterol levels are influenced by several non-dietary factors and HDL levels do not explain differences in CHD mortality between populations. HDL levels are increased by alcohol, weight loss, and by physical activity. Populations who have high intakes of mono-unsaturated fatty acids (from olive oil) or have diets rich in n-3 polyunsaturates of marine origin (like Eskimos) also have low CHD rates. Both *mono-unsaturated* and n-3 and n-6 *polyunsaturated fatty acids* (PUFAs) lower plasma total and LDL cholesterol; PUFAs are more effective than monounsaturates (Kris-Etherton 1999; Mori and Beilin 2001). There is good evidence that some isomers of fatty acids, such as *trans fatty acids*, increase the incidence of CHD by increasing LDL cholesterol levels and decreasing the HDL levels, by interfering with essential fatty acid metabolism and by enhancing the concentrations of the lipoprotein Lp(a) which, in genetically susceptible people, seems to be an additional risk factor through mechanisms which include an antiplasminogen effect to limit fibrinolysis.

Other dietary components, for example, *dietary fibre* or *complex carbohydrates*, seem to influence serum cholesterol levels and the incidence of CHD. Populations consuming diets rich in plant foods high in complex carbohydrates have lower rates of CHD; vegetarians have a 30 per cent lower rate of CHD mortality than non-vegetarians and their serum cholesterol levels are significantly lower than that of lacto-ovo-vegetarians and non-vegetarians. *Alcohol* consumption also reduces the incidence of CHD. A number of observational studies suggest that light-to-moderate drinkers

Table 2.7.5 Summary of strength of evidence of dietary and lifestyle factors and risk of developing cardiovascular disease

Evidence	Decreased risk	No relationship	Increased risk
Convincing	Regular physical activity	Vitamin E supplements	Myristic and palmitic acids
	Linoleic acid		Trans fatty acids
	Fish and fish oils ¹		High sodium intake
	Vegetables and fruits		Overweight
	Potassium		High alcohol intake ⁴
	Alcohol intake (low to moderate) ²		
Probable	α Linolenic acid	Stearic acid	Dietary cholesterol
	Oleic acid		Unfiltered boiled coffee
	NSP ³		
	Wholegrain cereals		
	Nuts (unsalted)		
	Plant sterols/stanols		
	Folate		

Notes:

have a slightly lower risk of CHD than abstainers. However, the relationship between alcohol intake and CHD is complicated by changes in blood pressure and also the nature of the alcoholic drink. The presence of phenolic compounds in red wine may contribute to the benefits of drinking red wine as compared to alcohol consumption per se in reducing the risk.

The risk of CHD in individuals is dominated by three major factors: (1) high serum total cholesterol, (2) high blood pressure, and (3) cigarette smoking (WHO 1982). There is also a synergism between risk factors, with the Japanese notable for their high smoking rates and hypertension but very low cholesterol levels: smoking and hypertension are particularly harmful to individuals with high cholesterol levels. Body weight changes induced by diet and levels of physical activity, are strongly related to changes in serum total cholesterol, blood pressure, and obesity. Obesity in turn, particularly when associated with high waist circumference or waist/hip ratio, is strongly related to diabetes mellitus, both of which are risk factors for CHD.

Hypertension and stroke

The risk of CHD and that of cerebrovascular disease presenting clinically as stroke, increases progressively throughout the observed range of blood pressure, in a number of different

countries (MacMohan et al. 1990). From the combined data it appears that there is a fivefold difference in CHD and a tenfold risk of stroke over a range of diastolic blood pressure of only 40 mmHg. Analysis indicates that a sustained difference of only 7.5 mmHg in diastolic pressure confers a 28 per cent difference in risk of CHD and a 44 per cent difference in risk of stroke.

Nutritional determinants of hypertension are contributory and are causally linked to stroke. Obesity and alcohol intake are related to hypertension since weight reduction and restricting alcohol intake can lower blood pressures. The dietary factors that are implicated (in addition to alcohol and caffeine intakes) are excessive sodium and saturated fat intake and low potassium and calcium intake. The Intersalt Study (1988) compared blood pressure measurements with 24-hour urinary sodium excretion in 10,000 individuals aged 20–59 years in 32 countries and showed that populations with very low sodium excretion and intakes had low median blood pressures, a low prevalence of hypertension, and no increase in blood pressure with age. Although sodium intake was related to blood pressure levels and also influenced the extent to which blood pressures increased with age, the overall association between sodium, median blood pressure, and the prevalence of hypertension was less than significant. A number of explanations have been put forward to explain why studies such as the Intersalt Study underestimate the relationship between dietary sodium and blood pressure. These include among others: unreliability of assessing dietary intake of sodium accurately, genetic variability, and the contribution of other factors such as obesity or alcohol intake.

Reviews based on meta-analysis correlated blood pressure recordings in individuals with measurements of their 24-hour sodium intake (Law et al. 1991); an association increasing with age and the initial blood pressure. The results of intervention trials of sodium restriction support this relationship. Aggregation of the results of 68 cross-over trials and ten randomized control trials of dietary salt reduction have shown that moderate dietary salt reduction over a few weeks lowers systolic and diastolic pressure in those individuals with high blood pressure (Law et al. 1991). It was estimated that such reductions in salt intake by population would reduce the incidence of stroke by 26 per cent and that of CHD by 15 per cent in Western countries. Reduction of salt in processed food would lower blood pressure even further and would prevent as many as 70,000 deaths per year in the UK. Results of therapeutic trials of drug therapy also support the fact that the incidence of stroke can be reduced if blood pressure is lowered, although the beneficial effect of lowering the incidence of CHD is lower than expected. A recent Cochrane review of 34 clinical trials (He et al. 2013) showed that a modest reduction in salt intake for 4 or more weeks causes significant and important falls in blood pressure in both hypertensive and normotensive individuals, irrespective of sex and ethnic group. The review supports the view that a long-term reduction in population salt intake will lower population blood pressure and thereby reduce cardiovascular disease. The observed significant association between the reduction in 24-hour urinary sodium and the fall in systolic pressure indicates that larger reductions in salt intake will lead to larger falls in systolic blood pressure. The current recommendation is to reduce salt intake to 5–6 g/day and this will have a major effect on blood pressure. This review indicates that further reductions to 3 g/day will have a greater effect and should become the long-term target for population salt intake.

The other dietary component that has been investigated by the Intersalt Study (1988) is potassium. Urinary potassium excretion, an assumed indicator of intake, was negatively related to blood pressure as was the urinary sodium/potassium concentration ratio. It has also been observed that potassium supplementation reduces blood pressure in both normotensive and hypertensive subjects (Cappuccio and MacGregor 1991). A recent systematic review of 22 randomized control trials (Aburto et al. 2013) supports the view that increased potassium intake reduces blood pressure in people with hypertension and has no adverse effect on blood lipid or catecholamine concentrations, or renal function. The higher potassium intake was associated with a 24 per cent lower risk of stroke. These results suggest that increased potassium intake is potentially beneficial to most people for the prevention and control of elevated blood pressure and stroke.

Some, but not all, cross-sectional and intervention studies suggest a beneficial effect of calcium intake on blood pressure. Epidemiological studies also consistently suggest lower blood pressures among vegetarians independent of age and body weight. These studies may also support the role of other dietary components because vegetarian diets rich in complex carbohydrates are also rich in potassium and other minerals.

Nutritional intervention is likely to reduce the occurrence of hypertension and the complications of stroke and CHD in the community, demonstrated in Finland where the average blood pressure has fallen by nearly 10 mmHg and the prevalence of hypertension is only a quarter of what it was prior to the intervention. Along with the falls in average cholesterol levels, CHD and stroke rates in Finland have fallen dramatically as the population's diet was transformed to change its fat content and to more than double the average vegetable and fruit intakes. The decline in CHD and stroke rates was predominantly dependent on the fall in cholesterol and blood pressure levels respectively and these changes occurred despite increasing obesity rates (Puska et al. 1995).

A summary of the strength of evidence (convincing and probable) on diet and lifestyle factors and risk of developing cardiovascular diseases (CHD and stroke) based on the recent Joint WHO/FAO Expert Consultation is provided in Table 2.7.5 (WHO/FAO 2003). There is now general agreement on the population strategies that need to be adopted to reduce both the frequency and extent of the risk factors of cardiovascular disease based on this report. The nutritional approach including increasing physical activity is aimed at reducing obesity, lowering blood pressure, lowering total and LDL cholesterol and increasing HDL cholesterol, and lowering sodium intakes. Current recommendations take into consideration both the entire spectrum of cardiovascular risks including effects on thrombosis as well as providing a holistic approach to recommending a healthy diet that will reduce all chronic NCDs including cancers. These recommendations include lowering total fat intake to between 30 to 35 per cent of total calories, restricting saturated fat intake to a maximum of 10 per cent of total calories, and increasing contribution from monounsaturated and polyunsaturated fatty acids (n-3 and n-6 PUFAs) and to increase intakes of complex carbohydrates or dietary fibre. Translated into food components this would mean reducing in particular intake from animal fat, hydrogenated and hardened vegetable oils, and increasing the consumption of cereals, vegetables, and fruits. Dietary advice appears to be effective in bringing about modest beneficial changes

in diet and cardiovascular risk factors over approximately a year (Rees et al. 2013).

Diet nutrition and cancers

It is now widely accepted that one-third of human cancers could relate directly to some dietary component (Doll and Peto 1981) and it is probable that diet plays an important role in influencing the permissive role of carcinogens on the development of many cancers. Thus up to 80 per cent of all cancers may have a link with nutrition.

Evidence that diet is a determinant of cancer risk comes from several sources. These include correlation between food consumption data and the incidence of cancers in the population. Studies on the changing rates of cancer in populations as they migrate from a region or country of one dietary culture to another have contributed to many important hypotheses. Case-control studies of the dietary habits of individuals with and without a cancer and prospective studies as well as intervention trials have provided evidence for the effects of diet on cancer. Only those human cancers where the role of diet or a nutrient is reasonably well established (summarized in Table 2.7.6) are discussed here.

Cancers of the gastrointestinal tract may be influenced by the diet. The intake of alcohol appears to be an independent risk factor for oral, laryngeal, and pharyngeal cancers as well as for oesophagus, liver, and breast cancers. Consumption of salted fish (Cantonese style), preserved, and fermented foods containing nitrosamines as weaning foods or from early childhood may introduce a substantial risk of *nasopharyngeal cancer*. *Stomach cancer* is also associated with diets comprising large amounts of salted and salty foods and low levels of fresh fruit and vegetables which may contain nutrients that possibly inhibit the formation of nitrosamines. Non-starchy vegetables, allium vegetables (onion, garlic, etc.), and fruits probably decrease risk of stomach cancer.

Cancers of the colon and rectum are the third commonest form of cancer and the incidence rates are high in Western Europe and North America while they are low in sub-Saharan Africa (Boyle et al. 1985). International comparisons indicate that diets low in dietary fibre and high in animal fat and animal protein increase the risk of colon cancer. The epidemiological data relating dietary fibre to colorectal cancer generally support the existence of an inverse relationship between the intake of foods rich in dietary fibre and colon cancer risk and meta-analysis indicates a 10 per cent decreased risk per 10 g fibre per day. Diets rich in fibre are also rich sources of antioxidant vitamins and minerals with potential cancer inhibiting properties. Vegetarian diets seem to provide a protective effect from the risk of colon cancer. There is now convincing evidence that red meat and processed meat in the diet increases the risk of colon and colorectal cancers while physical activity decreases risk. Alcohol intake in men and women as well as obesity and abdominal fatness increase risk of this cancer (World Cancer Research Fund and American Institute for Cancer Research 2007; Vargass and Thompson 2012).

Primary *liver cancers* have been correlated with mycotoxin (aflatoxin) contamination of foodstuffs.

The primary causal factor for *lung cancer*, a leading cause of death among men, is cigarette smoking. Several studies have shown an interactive effect between cigarette smoking and low frequency of intake of green and yellow vegetables rich in β -carotene. In prospective studies, the frequency of the consumption of foods

Table 2.7.6 Associations between nutritional factors and some common cancers

Cancer	Decreasing risk of cancer	Increasing risk of cancer
Breast	Lactation Physical activity	Alcohol Obesity
Colorectal	Physical activity NSP ¹ /dietary fibre Milk, calcium	Processed red meat Alcohol Obesity
Endometrium, and kidney	Physical activity	Obesity
Liver		Aflatoxin Alcohol
Lung	Fruits Physical activity	High-dose supplements of β -carotene
Mouth, larynx, pharynx	Vegetables and fruits	Alcohol
Nasopharynx		Salted fish ²
Oesophagus	Fruits and vegetables	Alcohol Obesity
Pancreas	Folate rich foods	Obesity
Prostate	Lycopene and selenium rich foods	High calcium diets
Stomach	Fruits and vegetables	High salt intake

Notes:

Both convincing and probable evidence for decreasing and increasing risk combined.

¹ NSP, non starch polysaccharide/dietary fibre

² Specifically Cantonese style salted fish

rich in β -carotene has been inversely associated with lung cancer risk. However, high intakes of β -carotene as supplements increase risk significantly; and so does arsenic in drinking water.

Breast cancer is a common cause of death among women both in the United States and in the United Kingdom. The most convincing evidence is that lactation protects against risk of breast cancer in both pre- and postmenopausal women. Physical activity probably also decreases risk while increases in body fatness after menopause increases risk. While other nutritional factors such as greater birth weight, attained adult stature, and weight gain increase risk, consumption of alcoholic drinks also convincingly increases risk of breast cancer both pre- and post-menopause.

Dietary factors are important in the causation of cancers of many sites and dietary modifications may reduce cancer risk. In general diets high in plant foods, especially vegetables and fruits, are strongly associated with a lower incidence of a wide range of cancers. Such diets tend to be low in saturated fat, high in complex carbohydrate and fibre, and rich in several antioxidant vitamins. Sustained and consistent intake of alcohol, physical inactivity, and obesity and body fatness are also associated with several cancers. On the basis of the evidence, a recent report (World Cancer Research Fund and American Institute

for Cancer Research 2007) makes the following recommendations: (1) be within the normal range of body weight for height and be physically active; (2) eat mostly foods of plant origin and limit intake of red meat and avoid processed meat; (3) limit consumption of energy dense foods and avoid sugary drinks; (4) limit alcohol intake; (5) limit consumption of salt, and avoid mouldy food; (6) mothers must be encouraged and supported to breastfeed their children.

Diet, lifestyles, and obesity

Obesity is one of the most important public health problems and the prevalence of obesity is increasing worldwide. In developing countries undergoing rapid economic growth, relatively affluent and urbanized communities are showing an increasing prevalence of obesity among adults and children.

Overweight and obesity is normally assumed to indicate an excess of body fat. Like adult undernutrition, BMI is used as an indicator of choice for obesity and Table 2.7.7 outlines the diagnostic criteria for overweight and obesity in infants and children, adolescents and adults (WHO 1995, 2000). Recent recommendations are that a BMI of between 18.5 and 24.9 in adults be considered appropriate weight-for-height; BMI between 25 and 29.9 be indicative of overweight and possibly a pre-obese state; while obesity is diagnosed at a BMI greater than 30.0.

The main health risk of obesity is premature death due to heart disease and hypertension and other chronic diseases. In the presence of other risk factors (both dietary and non-dietary), obesity increases the risk of CHD, hypertension, and stroke. In women, obesity seems to be one of the best predictors of cardiovascular disease. Longitudinal studies have demonstrated that weight gain, both in men and women, is significantly related to increases in

cardiovascular risk factors. Weight gain was strongly associated with increased blood pressure, elevated plasma cholesterol and triglycerides, and hyperglycaemia. The distribution of fat in the body in obesity may also contribute to increased risk; high waist-hip ratios (i.e. fat predominantly in abdomen and not subcutaneous) increase the risk of heart disease and type 2 diabetes. The coexistence of diabetes is also an important contributor to morbidity and mortality in obese individuals. Obesity also carries increased risk of gall bladder stones, breast and uterine cancer in females, and possibly of prostate and renal cancer in males, as well as osteoarthritis of weight-bearing joints and obstructive sleep apnoea. While obesity contributes to social problems such as low self-esteem and reduced employability it is also associated with increasing mortality both in smokers and non-smokers.

Several environmental factors, both dietary and lifestyle related, contribute to increased obesity. Social and environmental factors that either increase energy intake and/or reduce physical activity are of primary interest. Changes in the environment that affect the levels of physical activity and changes both in the food consumed and in the patterns of eating behaviour may contribute to increase energy intakes beyond one's requirement, thus causing obesity. Increased intake of dietary fat as energy-dense food may result in poor regulation of appetite and food intake while fibre-rich complex carbohydrates tend to bulk the meal and limit intakes.

International comparisons reveal that obesity increases as the fat percentage of calories in the diet increases (Lissner and Heitmann 1995). A recent systematic review indicates that increased intake of sugars was associated with increase in body weight while iso-energetic exchange of dietary sugars with other carbohydrates showed no change in body weight (Morenga et al. 2013). Patterns of eating, particularly snacking between meals, may contribute to increased intakes. However, evidence supports the view that much of the energy imbalance in modern societies is largely the result of dramatic reductions in physical activity levels (both occupational and leisure time) when food availability is more than adequate.

Tackling overweight and obesity that is approaching epidemic proportions worldwide is of crucial importance since it is associated with several co-morbidities and the consequent increased healthcare costs. It has been estimated that the direct costs of obesity for healthcare in the United States in 1995 were US\$ 70 billion and those of physical inactivity another US\$ 24 billion (Colditz 1999). These are enormous costs and a huge drain on healthcare budgets of countries.

Preventive measures to tackle the increasing obesity worldwide are reliant on the strength of evidence related to the factors that increase or reduce the risk of weight gain. The WHO report (WHO and FAO 2003) and a more recent review of the evidence is provided in Table 2.7.8 (World Cancer Research Fund and American Institute for Cancer Research 2007). Preventive measures have to start very early and primary prevention may have to be aimed at young children. This includes nutrition education of children and parents and dealing with problems of school meals, snacking, levels of physical activity, and other related issues. Public health initiatives need to address all social and environmental issues that contribute to the increasing energy and fat intakes and reductions in physical activity. Since the issues are complex, attempts have to be made to interact with a wide range of stakeholders and address issues relevant to work sites, schools, supermarkets, and deal with marketing, advertising, and promoting activity, etc., and

Table 2.7.7 Diagnostic criteria for overweight and obesity in infants and children, adolescents and adults

Infants and children (all ages)	Weight-for-height	>+ 2 Z scores
Adolescents		
Overweight	BMI-for-age	>85th percentile
Obese	BMI-for-age	>85th percentile of BMI plus
	Triceps-for-age	>90th percentile of TSKF
	Subscapular-for-age	>90th percentile of SSSKF
Adults		
Normal weight range	BMI	18.5–24.9
Overweight or pre-obese	BMI	25.0–29.9
Obese—Grade I	BMI	30.0–35.9
Grade II	BMI	35.0–39.9
Grade III	BMI	> 40.0

SSSKF, supraspinal skinfold thickness; TSKF, triceps skinfold thickness.

not merely expect the health sector to provide solutions. A recent high-level exercise in the UK is a good example of such an integrated approach to the problem (Foresight 2007).

Type 2 diabetes mellitus

Type 2 diabetes mellitus (formerly non-insulin dependent diabetes mellitus) is a chronic metabolic disorder which occurs in adulthood and is strongly associated with an increased risk of CHD. Type 2 diabetes mellitus has to be distinguished from type 1 diabetes mellitus (formerly insulin dependent diabetes mellitus) and from gestational diabetes of pregnancy. Obesity is a major risk factor for the occurrence of type 2 diabetes mellitus; the risk being related both to the duration and the degree of obesity. The occurrence of type 2 diabetes mellitus appears to be triggered by environmental factors such as sedentary lifestyle, dietary factors, stress, urbanization, and socioeconomic factors. Certain ethnic or racial groups seem to have a higher incidence of type 2 diabetes mellitus; these include Pima Indians, Nauruans, and South Asians (i.e. Indians, Pakistanis, and Bangladeshis). Type 2 diabetes mellitus also seems to occur when the food ecosystem rapidly changes, for example, urbanization of Australian aborigines or adoption of Western dietary patterns by Pima Indians.

The cause of type 2 diabetes mellitus is unclear, but it seems to involve both an impaired pancreatic secretion of insulin and the development of tissue resistance to insulin. Overweight and obesity, particularly the central or truncal distribution of fat accompanied by a high waist-hip ratio and a high waist circumference, seems to be invariably present with type 2 diabetes mellitus. Hence the most rational approach to preventing type 2 diabetes mellitus is to prevent obesity. Weight control and increasing physical activity levels are fundamental both as a population strategy for the primary prevention of this disorder but also to tackle high-risk individuals. Physical activity improves glucose tolerance by weight reduction and by its beneficial effects on insulin resistance. Diets high in plant foods are associated with a lower incidence of type 2 diabetes mellitus and vegetarians have a lower risk.

Expert groups have provided dietary recommendations for both the primary prevention of type 2 diabetes mellitus, the

management of diabetes, and the reduction of secondary complications which include CHD risk and renal, ocular, and neurological complications of diabetes. Prevention of weight gain and reduction of obesity is the key, as is increasing levels of physical activity. The specific dietary recommendations include providing diets with carbohydrates contributing 55–60 per cent of energy, maximizing content of complex carbohydrates and dietary fibre, and reduction of simple sugar intakes. In addition the general recommendations for fat (saturated fat to <10 per cent of calories) are emphasized due to the associated high risk of CHD. Maintaining a desirable body weight and preventing weight gain is most important.

Diet and osteoporosis

The increase in numbers of the elderly in the developed world has seen an increase in their health problems, which affects their quality of life. Fracture of the hip is an important health problem, particularly among postmenopausal women. Fractures occur in the elderly following a relatively trivial fall when there is osteoporosis and the density of the bone is reduced. Bone density increases in childhood and adolescence and reaches a peak at about 20 years of age. Bone density falls from menopause in women and from about the age of 55 years in men. The variation in bone density between individuals and different racial groups is large and of the order of ± 20 per cent. Since bone density declines with increasing age, those that attain high levels of peak bone mass at the end of adolescence and retain higher levels of bone density during adulthood become osteoporotic with advancing age much more slowly than those with lower bone densities to start with. Hence factors that influence the attainment of peak bone density may play a crucial role in the development of osteoporosis and the occurrence of fractures with ageing.

Several factors influence the onset of osteoporosis and include the lack of oestrogen in postmenopausal women, degree of mobility, smoking, and alcohol intake. Calcium intake may influence the onset and degree of osteoporosis. Evidence from some countries indicates that osteoporosis may be diet related since the fracture rate is halved among individuals in the higher calcium intake range. However, there are regions where the lower rates of fracture and osteoporosis are associated with lower calcium intakes. The rates are lower in Singapore compared to the United States, although the calcium intakes are lower than the United States. The traditional emphasis on calcium intakes possibly reflects the recognition of its importance in contributing to the density of bone during growth and the need for attaining dense bones at the peak of adult life. High protein and high salt diets are known to increase bone loss while calcium supplements, well above what may be considered physiological, in postmenopausal women, may reduce the rate of bone loss and slow down osteoporosis. Adequate levels of vitamin D are important factors that diminish risk of osteoporosis. Poor vitamin D status has been linked with age-related bone loss and osteoporotic fractures in the elderly.

Other nutrients may be important for long-term bone health and the prevention of osteoporosis. Consumption of dairy products, fruits, and vegetables are important modifiable protective factors for bone health, and nutrients like magnesium, potassium, vitamins C, K, and B, and carotenoids have been shown to be more important than previously realized (Tucker 2009). Current research on diet and bone status supports

encouragement of balanced diets with plenty of fruit and vegetables, adequate dairy and other protein foods, and limitation of foods with low nutrient density. Moderate alcohol intake shows positive effects on bone, particularly in older women, while high intakes of alcohol increase risk of osteoporosis. Convincing evidence indicates that physical activity is an important determinant of bone health.

It is generally believed that populations in developing countries are at less risk of developing osteoporosis in spite of low calcium intakes. This may be related to the fact that they do more physical work, smoke less, drink less alcohol, and have diets which are generally not high in protein or salt content. However, osteoporosis is seen in developing countries in regions where low intakes of dietary calcium are associated with high fluoride intakes. No osteoporosis occurs if high intakes of fluoride are accompanied by dietary intakes of calcium which are also high.

Diet and dental caries

Dental caries is a common disease of the teeth, which results in decay of the tooth surface, usually beginning in the enamel. An essential feature in the causation of dental caries is dental plaque which is largely made up of microorganisms. Dietary sugars diffuse into the dental plaque where they are metabolized by the microorganisms to acids which can dissolve the mineral phase of the enamel causing dental decay. The process is, however, much more complex and is related to the quantity and quality of saliva produced in the mouth among other factors.

The evidence relating diet to dental caries has been well reviewed and overwhelming evidence indicates that sugars are cariogenic. Good correlations exist between the sugar supply and the occurrence of dental caries in children and adults (WHO and FAO 2003). The consumption of refined sugar in many parts of the world seems to be accompanied by an increase in dental caries in communities which were hitherto free of the problem. Cross-sectional studies demonstrate good correlations between sugar consumption and incidence of dental caries, particularly among young children. Consumption of sugars between meals is associated with a marked increase in caries compared to consumption of sugars with meals. Sucrose is the predominant dietary cariogenic agent, although the current emphasis is on the consumption of all free sugars, particularly between meals. Analysis of epidemiological data from several countries suggests that a much closer relationship exists between dental caries and free sugars than between caries and starchy cereal foods. Fresh fruit, although it contains intrinsic sugars, has a lower cariogenic potential while fruit juices are cariogenic, which may be related to the added sugars in fruit juices or from the lack of adequate salivary stimulation. Food may also contain protective factors that prevent the occurrence of dental caries. This includes fluoride and inorganic phosphates in the diet which protect against dental caries.

Prevention of dental caries can be achieved by health education aimed at the individual beginning in infancy. Avoidance of the addition of free sugars to bottle feeds and milk and fruit drinks are a must. An adequate intake of fluoride is desirable quite early in life. During childhood and adolescence, the restriction of the three major sources that contribute to two-thirds of our intake of sugars, i.e. confectionery, table sugar, and soft drinks, will help reduce the increment of caries in childhood. At local and national level, the main interventions should include fluoridation of water

supply, labelling of foods, and possible changes in policies that promote the production and marketing of free sugars.

Population nutrient intake goals in the prevention of chronic diseases

The distribution and determinants of risk factors in a population have direct implications for population-based prevention strategies. Risk typically increases across the spectrum of the risk factor and is a continuum. Thus, individuals at increased risk are not a distinct group or deviant minority, but a part of the risk continuum. Hence population-based strategies must seek to shift the whole distribution of risk factors downwards and thus reduce population incidence of the disease.

Population nutrient intake goals represent the mean population intake of the nutrient that is judged to be consistent with the maintenance of good health, i.e. a low prevalence of diet-related diseases in the population. There is no single best value and the safe range of intakes that constitute the nutrient goals would be consistent with maintenance of health. If the existing population averages move outside the recommended ranges, health concerns are likely to arise. Thus population nutrient intake goals are useful signposts for population-based strategies to help shift the risk distribution in a population downwards and thus reduce risk of the disease. The recommended population nutrient goals based on critical examination of the evidence from an Expert Consultation (WHO/FAO, 2003) are summarized in Table 2.7.9.

Emerging food and nutrition issues of public health concern

Over the last decade several issues of public health concern related to food and nutrition have emerged globally. These include

Table 2.7.9 Ranges of the population nutrient intake goals

Dietary factor/nutrient	PNI goal ¹
Total fat	15–30%
Saturated fat	< 10%
Polyunsaturated fatty acids (PUFAs)	6–10%
n-6 PUFAs	5–8%
n-3 PUFAs	1–2%
Trans fatty acids	< 1%
Monounsaturated fats (MUFAs)	By difference
Total carbohydrate	55–75%
Free sugars	<10 %
Protein	10–15%
Cholesterol	< 300 mg per day
Sodium chloride	<5 g per day
Fruits and vegetables	> 400 g per day

Note: ¹ expressed as per cent of energy.

problems related to microbiological safety of foods, concerns related to genetically modified foods, issues of labelling of processed foods, and the emerging epidemic of diet-related chronic diseases and obesity.

Food safety

Food safety refers to whether food is safe for human consumption and hence lacking in biological and chemical contaminants that have the potential to cause illness. The increasing concern over the safety of foods in the West is a paradox in that the epidemiological evidence on the safety of foods is quite contrary to the perceptions of the public and the media that the food available now is less safe than it used to be. The improvements in public health have virtually eradicated primarily food-borne infections that were associated with morbidity and mortality. The common food-borne diseases currently encountered in the West are usually associated with mild self-limiting gastroenteritis. Studies of risk perception suggest that the public becomes alarmed by health threats which are disproportionate to the actual risk associated with the disease and that this public concern is fuelled by the media which make health issues into media health scares depending on the newsworthiness of the incidents.

There have been several food-borne epidemics that have raised concerns about food safety in recent years. These include for instance the *Salmonella enteritidis* pt4 (Se4) epidemic. This was attributed to the ability of Se4 to invade the oviduct of poultry and get deposited in the albumin of the egg. At the consumer level the outbreak of the infection was linked to the use of raw egg in recipes or cross-contamination from raw to cooked foods. *Campylobacter* infection is the commonest food-borne disease in the UK and the increase in its incidence may partly be explained by the better ascertainment and reporting of cases with this infection. The more recent food scare was the emergence of *Escherichia coli* O157 in Scotland which caused several deaths and was attributable to changes in husbandry and the movement of livestock and the rapid growth of the fast food industry. *Listeria* is another cause of food-borne disease exemplifying of the role of globalization and international trade in the spread of food-borne diseases.

In the developing world the issues of food safety are related to microbiological agents that contaminate food and water and spread disease rapidly in the warm humid environments aided by the improper or poor food hygiene practices, poor environmental sanitation, and inadequate regulation of food-related commerce. The safety of foods in the developing world is also compromised by the presence of toxins like aflatoxins due to poor food storage practices or due to cyanogens in the diet due to inadequate preparation of foods such as cassava. Aflatoxins are linked to hepatocellular cancer and the risk appears to be higher among those who are likely to be hepatitis B positive. In addition, the food chain in poor countries is contaminated by pesticide and chemical residues compromising the safety of the food consumed by populations in these countries.

Genetically modified foods

Another issue that has created a considerable degree of controversy is the use of biotechnology to produce genetically modified (GM) foods. Genetic modification of food crops can be used to reduce food losses by increasing resistance to drought, frost, diseases, and pests and help control weeds and reduce post-harvest

losses. Biotechnology can improve the nutritional value of foods, for example, by increasing protein or micronutrient content or by reducing saturated fat content. They could help slow down ripening so that foods retain their quality much longer. Biotechnology can increase both the yield and the quality of crops grown on existing farmland and thereby reduces pressure on wildlife habitats. In the West, particularly in the United Kingdom and Europe, the opposition to GM foods is based largely on arguments that raise concerns with ecological damage that may follow large-scale use of GM crops.

In developing countries the concerns are more related to the use of the 'terminator gene' technology and the dependence on the large multinationals for seeds and chemicals that the small farmers will inherit. At the heart of this controversy and the raging debate is the gulf between plant breeders, seed and agrochemical industries who promote biotechnology, and the campaigners who argue that GM technology may have hazardous consequences on the environment. This is a debate replete with numerous paradoxes and the climate of mistrust, some of it associated with the bovine spongiform encephalopathy and new variant Creutzfeldt-Jakob disease scare, and is obscuring the real issues and clouding objective decisions from being made with regard to the production and consumption of GM foods (Dixon 1999).

Agricultural biotechnology is essential to increase food production to an increasing global population that is increasingly diverting food from human use to biofuels and animal feed; the latter the consequence of increased meat consumption with economic growth, as seen in China. It has the potential to improve the quality and the nutrient content of the food to address both nutritional needs that pose public health challenges (such as iron, zinc, and vitamin A deficiencies) as well as consumer demands. It is interesting to note that the perception and acceptance of GM foods in developing societies is at variance to the concerns in developed countries (FAO 2004). Agricultural biotechnology will have an important role to play if emphasis is placed on agriculture and farming systems as a means to sustainably improve nutrition.

Food labelling

An important source of information for the consumer about the food on the supermarket shelf is the label on a food product. Food labels provide information that may be of interest to the consumer, especially with regard to the added chemicals (additives, pesticide residues, colouring and flavouring agents, and preservatives), fats, sugars, and energy content. Although about two-thirds of shoppers claim to read the information on the labels of new or unfamiliar food products to check their contents, this interest in labels does not mean that consumers always understand the information in the labels. Consumers are even more confused by the nutrition information panel which appears on many food labels.

Food label information is usually designed by experts. A prototype label was produced by the *Codex Alimentarius Commission* of the FAO and WHO, which is the organization charged with advising on international food standards, and this prototype is followed by Food Standards Committees around the world. According to this prototype the nutrients—energy, carbohydrate, protein and fats—are listed according to their amounts per serving and per 100 g. Most consumers, however, have hardly any idea of what a 100 g serving is, or for that matter what a normal or average serving is. A further problem is that these labels designed

by experts are also beset with problems with terminology. Health benefits or nutritional claims are not meant to be part of the food labels and they also do not provide information to cover ecological and ethical issues which may be of concern for some consumers. More recently the need to highlight the source or origin of foods and in particular the labelling of GM sources of the food product has been a serious concern of consumers. In January 2007, the Food Standards Agency in the United Kingdom agreed on the nutritional criteria for a 'traffic light' labelling of food products to identify products high in fat, sugar, and/or salt. Consumer organizations supported this move while some of the major food companies and supermarkets initially opposed the scheme. In recent years there is generally more acceptance of this simple labelling scheme. Food labelling is an important issue of public health concern and despite the considerable progress made so far there is much to be achieved.

Functional foods

New food products are being marketed as health-enhancing or illness-preventing foods. These are called functional foods or otherwise 'pharmafoods', 'nutriceuticals', or novel foods. Functional foods are generally defined as food products that deliver a health benefit beyond providing nutrients. The health benefits of functional foods may be conferred by a variety of production and processing techniques which include: fortification of certain food products with specific nutrients, using phytochemicals and active microorganisms, and by genetic modification of foods. The topic of functional foods is complex and controversial. An assumption implicit in the functional foods and health benefit claims is that the food supply needs to be fixed or doctored (or medicalized) on public health grounds. The assumption therefore is that the current food supply is in some way deficient, that the habitual diets are inadequate, and a technological fix will solve the problem. Thus the emerging debate viewed from the perspective of the proponents of functional foods is that these novel foods may reduce healthcare expenditure by promoting good health and that functional foods are a legitimate nutrition education tool, which will help inform consumers of the health benefits of certain food products. The opponents on the other hand rightly state that it is the total diet that is important for health. They believe that the functional foods are a 'magic bullet' approach which enables manufacturers to indulge in marketing hyperbole, exploit consumer anxiety, and essentially blur the distinction between food and drugs. Ironically the production and marketing of functional foods is on the rise in most developed countries. Regulatory bodies in developed societies have a huge and uphill task ahead to ensure that health claims made for these novel foods is evidence based.

Emerging epidemic of obesity and diet-related chronic diseases and the 'double burden' of malnutrition in developing societies

A critical examination of the principal causes of mortality and morbidity worldwide indicates that malnutrition and infectious diseases continue to be significant contributors to the health burden in the developing world. Although reductions in the prevalence of undernutrition are evident, the numbers of individuals affected remain much the same or have even increased, largely due to increases in the population. What is striking, however, is

that the health burden due to NCDs is dramatically increasing in some of these developing countries with modest per capita GNPs, particularly among countries in rapid developmental transition. Even the modest increases in prosperity that accompany economic development seem to be associated with marked increases in the mortality and morbidity attributable to these diet-related NCDs. These transitions in the disease burden of the population are mediated by changes in the dietary patterns and lifestyles that typify the acquisition of urbanized lifestyles.

Most developing countries, particularly those in rapid developmental transition, are in the midst of a demographic and epidemiological transition. Economic development, industrialization, and globalization are accompanied by rapid urbanization. These developmental forces are bringing about changes in the social capital of these societies as well as increasing availability of food and changing lifestyles. The changes in food and nutrition are both quantitative and qualitative; there is not only access to more than adequate food among some sections of the population, but also a qualitative change in the habitual diet. Lifestyle changes contribute to a reduction in physical activity levels. The essence of these changes is captured by the term 'nutrition transition' (Popkin 1994) which accompanies the demographic and epidemiologic transition in these countries. The poor consumer resistance and inadequate regulation compromises food safety and increases contaminants in the food chain. In addition the deterioration of the physical environment, particularly the increase in levels of environmental pollution, contributes to the health burden. Developing societies suffer a 'double burden'—an unfinished agenda of pre-existing widespread undernutrition superimposed by the emerging burden of obesity and NCDs.

Food and nutrition in the prevention of diseases of public health importance

The public health approach to the prevention of nutrition-related diseases requires the adoption of health-oriented nutrition and food policies for the whole population. In most developing countries, the first priority must be ensuring the production or procurement of adequate food supply and its equitable distribution and availability to the whole population along with the elimination of the various forms of nutritional deficiencies. Efforts must also be made to improve the quality of the food which includes ensuring food safety while reducing spoilage and contamination of foods as well as diversifying the availability and use of foods. In agrarian societies, consideration must be given to the short- and long-term effects of agricultural policies which affect the income and buying power of the small producers. Particular attention needs to be paid to the impact the promotion of cash and export crops has on the availability and ability to procure the principal staples in the diet. Special attention needs to be paid to the feasibility of fortification of foods to deal with localized or widespread deficiencies of iodine, iron, and vitamin A as a mass intervention measure.

In developed countries, the burgeoning costs of tertiary healthcare related to the diagnosis and management of the increasing burden of obesity and NCDs have had an impact. There is increasing recognition of the need for prevention-oriented health and nutrition policies and changes in behaviour and lifestyle to reduce the occurrence of these diseases. Some developed countries have been active in the field of public education using national dietary

guidelines as a major stimulus. It is important to remember that nutrition education of the public operates in the area where advice is given on a balance of probabilities, rather than irrefutable evidence or any degree of certainty. There is bound to be information that does not fit in with the consensus view since the consensus is based on the balance of the available evidence. It is important to recognize that the causes of these chronic diseases are complex and dietary factors are only a part of the explanation. Individuals differ in their susceptibility to the adverse health effects of specific dietary factors or deficiencies of others. Within the context of public health the focus is the health of the whole population and interventions are aimed at lowering the average level of risk.

Changes in consumer preferences have emerged, initially among the upper socioeconomic and educated masses. The media attention, along with the behavioural changes in food preferences and food choices, are in turn influencing the industry to modify the systems for food production and processing. However, progress in changing consumer behaviour and preferences is by its nature intrinsically rather slow and has until recently largely occurred without support from public policies in any but the health sector. The process of changing unsatisfactory dietary practices and thus promoting health is not easy to achieve. Despite these limitations the occurrence of and mortality associated with some NCDs such as heart disease have declined, reflecting changes in lifestyles of populations.

The dynamic relationship between changes in a population's diet and changes in its health is reflected well in two critical situations. One is the changes in disease and mortality profiles of migrant populations moving from a low-risk to a high-risk environment. An example is the change in disease pattern of Japanese migrants to the United States. The other is the rapid change seen within a country as rural to urban migration occurs or more frequently as a developing country undergoes rapid industrialization and economic development and in the process acquires a dietary profile characteristic of developed countries. Several developing countries have urban pockets of affluent diet and lifestyles and related disease burdens in the midst of problems typical of a poor country. Such countries in transition, like India and Brazil, bear the dual burdens of diseases of affluence and the widespread health problems of a poor country. Developing countries can benefit by learning from the experience of dietary change and adverse health effects of the developed world. By recognizing this problem, governments of developing countries can gain for their people the health benefits of avoiding nutritional deficiencies without encouraging at the same time the development of NCDs that invariably accompany economic development.

It is thus possible for a country to achieve a reduction in infant and childhood mortality and an increase in life expectancy by the pursuance of health and nutrition policies that aim to provide adequate and equitable access to safe and nutritious food and to minimize at the same time the occurrence of diet-related chronic diseases. This in turn will help avoid the social and economic costs of morbidity and premature death in middle age—a period of highest economic activity and productivity to the nation and to society at large. If such a socially and economically desirable goal is to be achieved, then national governments worldwide must aim towards achieving a population-based dietary change (WHO 1990). In the pursuance of this objective UN agencies established

the scientific basis for Food Based Dietary Guidelines (FBDGs) (FAO and WHO 1996).

The development of food-based dietary guidelines

FBDGs are developed and used in order to improve the food consumption patterns and nutritional well-being of individuals and populations. FBDGs can address specific health issues without the need to fully understand the biological mechanisms that link constituents of food and diet with disease. FBDGs do take into account the considerable epidemiological data linking specific food consumption patterns with a low or high incidence of certain diet-related diseases.

Disseminating information and educating the public through FBDGs is a 'user friendly' approach since consumers think in terms of foods rather than nutrients. They provide a means for nutrition education and are intended for use by individual members of the general public, are written in ordinary language, and as far as possible avoid the use of technical terms in nutritional science. FBDGs will vary with the population group and have to take into account the local or regional dietary patterns, practices, and culture. It is important to underline that more than one dietary pattern is consistent with good health. FBDGs can serve as an instrument of nutrition policies and programmes. Since they are based directly on diet and health relationships of particular relevance to the individual country or region, they can help address those issues of public health concern, either dietary insufficiency or dietary excess. Food and diet are not the only components of a healthy lifestyle and it is important that other relevant messages related to health promotion are integrated into dietary guidelines.

Global strategies to reduce the burden of nutritional disorders

The prevalence of chronic diseases is increasing dramatically, with the majority occurring in developing countries. According to estimates made by WHO, 36 million people die annually from NCDs, 63 per cent of all global deaths are due to NCDs, and 9 million people die too young from NCDs, i.e. before the age of 60. WHO and the FAO earlier proposed an integrated global strategy for the prevention and control of NCDs entitled, 'Diet, physical activity and health' in 2003 and highlighted the fact that chronic diseases are the leading cause of disease and disability, but are neglected elements of the global health agenda (Beaglehole et al. 2007). They proposed a global goal for the prevention and control of chronic diseases to complement the MDGs. The goal is to reduce by 2 per cent per year the age-specific rates of death attributable to chronic diseases, achievement of which would avert 36 million deaths by 2015. Because most of the deaths averted would be in low- and middle-income countries and would mainly affect people less than 70 years, it would bring major economic benefits and reduce the health burden of these nations.

These efforts were followed up by a UN Summit on Non Communicable Diseases in 2011 that recognized 'the urgent need for greater measures at the global, regional and national levels to prevent and control non-communicable diseases'. Unfortunately, much of the emphasis of this summit was focused more on meeting the challenges to the health systems and health services than to prevention apart from tobacco. Dietary interventions to promote population health and reduce risk of NCDs received less attention.

Strategies that are developed to tackle global nutritional problems need to be joined up to deal simultaneously with both ends of the spectrum of nutritional disorders and need to encompass a wide range of stakeholders in an integrated manner to be effective.

The environment and climate change

Alistair Woodward and Alex Macmillan

Introduction to the environment and climate change

In 2006, George Pell, Archbishop of Sydney, compared those who seek cuts in greenhouse gas emissions with pagans who seek to pacify the gods by animal and human sacrifice. In both cases, he argued, spiritual emptiness and fears about the natural world lead to extreme and unreasonable behaviours (Pell 2006).

Cardinal Pell is not alone. Climate change attracts a lot of attention, and many people are prepared to express an opinion, often strongly worded and frequently poorly informed. This chapter aims to introduce readers to the basic science underlying climate change, so they are better placed to judge extreme claims of all kinds. We will explore the links between climate change and health, and examine the implications of this knowledge for public health policy and practice.

As a start, readers are invited to check their understanding of the field against the multiple-choice questions in Box 2.8.1. (The answers are shown at the end of the chapter in Box 2.8.4.) This is not a comprehensive test but a starting point and a guide to what is contained in the chapter.

The Earth has an average surface temperature suitable for life that is the product of a number of natural influences on the balance of radiation (radiative ‘forcing’ at the top of the atmosphere). These include solar activity (the amount of energy produced by the sun), the tilt and orbit of the planet, volcanic activity that injects gases and ash into the upper atmosphere, other dusts and aerosols that block incoming solar radiation, and the amount of reflection (‘albedo’) by clouds, ice, and snow. Also important is the concentration of so-called ‘greenhouse’ gases. These gases are transparent to relatively high-frequency incoming solar radiation in the visible spectrum. However, when this radiation is absorbed on the surface of the earth it is re-emitted in the infra-red range, which is trapped by the greenhouse gases. This action is similar to the effect of a pane of glass in a greenhouse (or the window of a car sitting in the sun). Without the blanket for the planet that is provided by the greenhouse gases, the Earth would be approximately 30 degrees centigrade (C) colder than it is at present. Carbon dioxide (CO₂) is the most abundant of these heat-trapping gases.

CO₂ levels in the atmosphere vary over long timescales due to transfers from the atmosphere to the biosphere and the oceans, and from the oceans carbon is eventually sequestered in sedimentary rocks. In the very long term, carbon from the earth’s crust is

ejected by volcanic eruptions into the atmosphere, and the cycle begins again.

What has changed in the last 200 years or so is the large-scale emission of CO₂ (and other heat-trapping gases) as a result of human activities, such as clearing of forests and burning of fossil fuels. This process began in pre-industrial times as a relatively minor addition of carbon to the atmosphere but has escalated rapidly in the last 50 years. In the early 2000s, roughly 27 giga-tonnes (Gt) of CO₂ were released into the atmosphere each year. (This equates to the mass of 3 million Eiffel Towers.) CO₂ is a long-lived greenhouse gas: about half of the carbon that is emitted into the atmosphere is taken up by natural sinks within 30 years, but about 30 per cent will persist in the atmosphere for centuries.

The concentration of CO₂ in the atmosphere has risen steadily from about 280 parts per million (ppm) in pre-industrial times, to 315 ppm in 1960 when direct measurements were first made, and exceeded 400 ppm in 2014. Indirect measures, using ice cores and other indications of historic conditions, tell us that the present levels are higher than at any time in the last 400,000 years. Concentrations of other, shorter-lived but more potent greenhouse gases, such as methane and nitrous oxide, have also increased acutely in the last 50 years (Solomon et al. 2007).

Consequences of these changes in atmospheric chemistry are evident in the recent temperature record at or close to the earth’s surface, and are expressed also in sea level rise, reduced snow and ice cover, and a variety of impacts on physical and biological systems. The year-to-year variability in average global temperatures is dominated by natural factors such as the El Niño Southern Oscillation (ENSO), so the effect of persistent, external forcing such as steadily rising greenhouse concentrations is seen most clearly on longer timescales. Indeed each of the last three decades has been warmer than all earlier decades, and the warmest years on record have occurred in the 2000s, according to NASA (Arndt et al. 2010). This rise in global average temperatures has occurred in every region, over both land and ocean, and cannot be explained by time trends in solar activity and other natural forcings. On the other hand, climate simulations that include anthropogenic contributions (i.e. the increase in CO₂ and other greenhouse gases) match well with the last 40 years of temperature records (Fig. 2.8.1).

Other evidence of global warming includes the predominance of highest ever temperatures in the record of temperature extremes (in the western United States, record high temperatures

Box 2.8.1 Carbon IQ quiz

Indicate which of the following, A to E, is the best answer for each question.

1. If the planet's atmosphere consisted of oxygen and nitrogen, the global average temperature would change by:
 - A. -30 degrees C
 - B. -10 degrees C
 - C. +10 degrees C
 - D. +30 degrees C
 - E. 0 degrees C
2. Climate is 'average weather'. Over what period?
 - A. At least a week
 - B. >2 years
 - C. >20 years
 - D. A century at least
 - E. Millennia
3. One-third of the CO₂ emitted today will still be in the atmosphere in:
 - A. 1 year
 - B. 10 years
 - C. 100 years
 - D. 1000 years
 - E. 10,000 years
4. Combustion of biomass releases black carbon, other particulates, and aerosols. The effect is to:
 - A. Warm
 - B. Cool
 - C. Affect regional climate, mostly
 - D. Accelerate ice melt
 - E. All of the above
5. In the last 50 years, what proportion of the warming due to greenhouse emissions has been absorbed by the ocean?
 - A. 5 per cent
 - B. 80 per cent
 - C. 0 per cent
 - D. 20 per cent
 - E. 100 per cent
6. Globally, the warmest year on record was:
 - A. 2010
 - B. 1998
 - C. 1992
 - D. 1980
 - E. 1260
7. How many return flights, Singapore to Rome, are required to generate the annual average emissions of CO₂ per capita for Laos?
 - A. 200
 - B. 20
 - C. 1
 - D. 0.2
 - E. 0.02
8. If there was a food with the energy intensity of oil, how many litres would be required to cycle 100 km?
 - A. 200
 - B. 20
 - C. 1
 - D. 0.2
 - E. 0.02
9. Which US President gave a commitment to translate the UN Framework Convention on Climate Change into 'concrete action to protect the planet'?
 - A. George H.W. Bush
 - B. Bill Clinton
 - C. George W. Bush
 - D. Jimmy Carter
 - E. Richard Nixon
10. Take the number of deaths in New Orleans caused by Hurricane Katrina, and make the numerator the average number of fatalities resulting from storms of a similar severity in Cuba in the preceding 5 years. The fraction is:
 - A. 0.1
 - B. 0.5
 - C. 2.0
 - D. 0.05
 - E. 1.0

now outnumber record low measurements each year by about three to one) (Meehl et al. 2009), and increasing temperatures in the upper layers of the ocean (which absorbs more than 80 per cent of the solar energy that is trapped by greenhouse gases) (von Schuckmann et al. 2009). Summertime Arctic sea ice is

reducing year on year, more rapidly than was forecast in the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report and global average sea level is rising at about 3.0 mm/year (twice the rate observed before 1990) (Australian Academy of Sciences 2010).

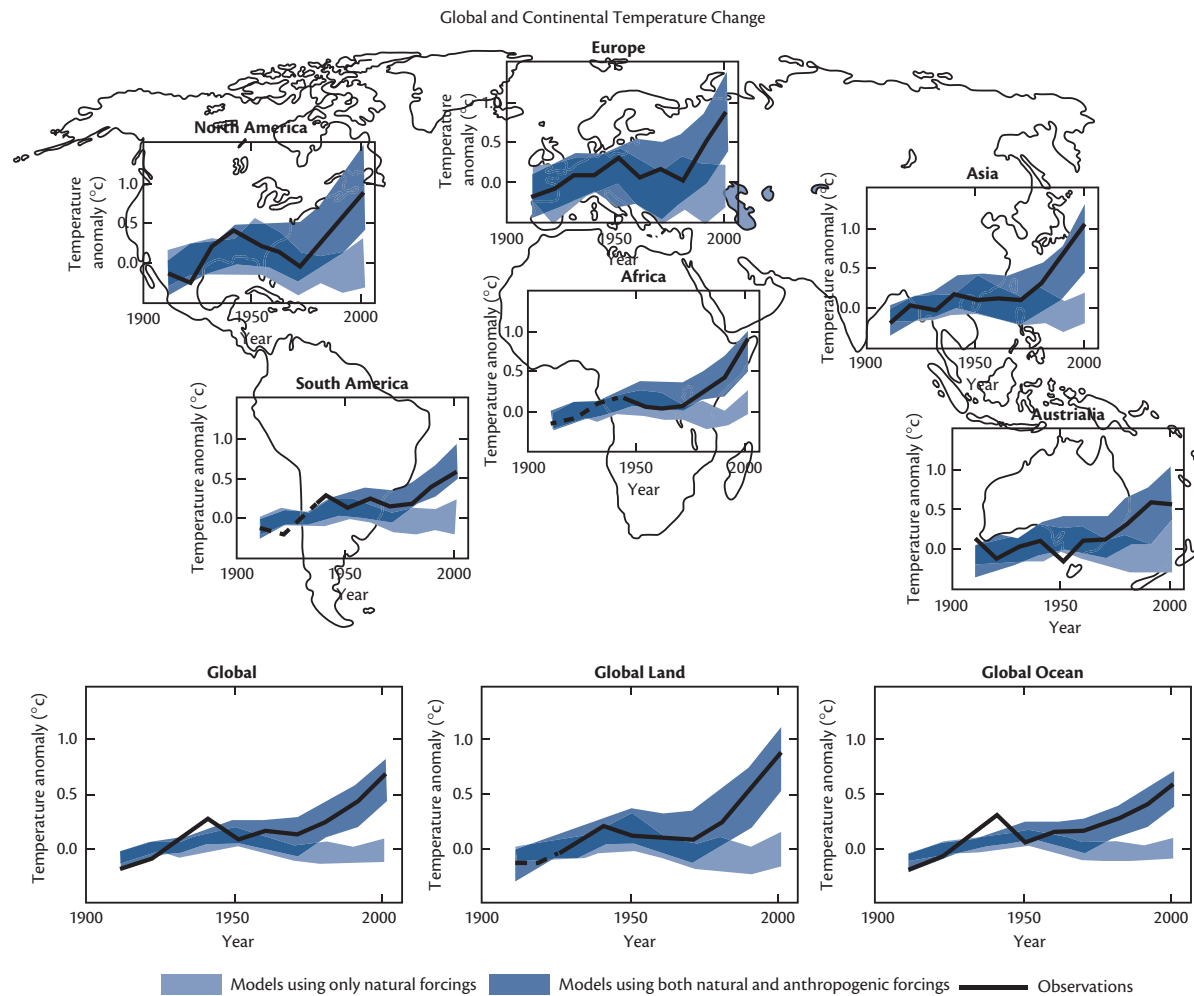

Fig. 2.8.1 Observed and modelled temperatures, 1906–2005. Decadal averages, observed (black lines), modelled using only natural forcings (lower shaded areas), and modelled using natural and anthropogenic forcings (upper shaded areas).

Reproduced with permission from *Climate Change 2007: The Physical Science Basis. Working Group I Contribution to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change*, Figure 2.5. Cambridge University Press.

Since the 1960s, emissions of greenhouse gases have tracked upwards, the rise halted only briefly by major economic disturbances, such as the Asian financial crisis of the late 1990s (Peters et al. 2011). Emissions in the first decade of the twenty-first century have matched, or exceeded, the figures forecast by the most extreme of the climate scenarios (A1FL) reported in the Third Assessment Report in 2001.

What about the future? The IPCC in AR4 forecast that the ‘business as usual’ trajectory would result in atmospheric CO_2 doubling pre-industrial levels sometime between 2050 and 2100, and global average temperatures rising as a result by between 2 and 4.5 degrees C by 2100 (Solomon et al. 2007).

A global average temperature rise reflects a shift of the whole temperature distribution to the right, but there will also be an increase in the variability of the distribution. This combination of distribution shift and increased variability translates a 2–4 degrees C increase (which may sound small) into a very marked increase in the frequency of very high temperatures that are presently experienced

rarely. It is projected that ‘mega-heatwaves’ of the kind that caused more than 50,000 excess deaths in Russia in 2010 may increase by a factor of 5–10 in Europe, within the next 40 years (Barriopedro et al. 2011). As average temperatures rise, the incidence of cold events is likely to fall, all else being equal, although there may be unexpected effects in some regions. In one example, melting of the Arctic ice has affected the high level jet stream over Europe and North America, and there is evidence of more severe winters occurring in these regions as a consequence (Liu et al. 2012).

The effects of warming and changes in rainfall will be unevenly distributed, geographically. For instance, a global average of 4 degrees C of warming may be associated with an increase in temperatures in the Arctic of 10 degrees C or more, a decline in rainfall by 40–50 per cent in North Africa, droughts threatening the viability of rain-fed agriculture in many parts of sub-Saharan Africa by the end of the century, and much of south-eastern Australia experiencing extreme fire risks as often as every second summer (4 degrees & beyond 2009).

In summary, the greenhouse effect is long known and well described. The rate at which greenhouse gas levels in the atmosphere are increasing is unprecedented in the last 400,000 years, and absolute concentrations are presently higher than at any time in the same period. In association with these changes, the world is warming, in a manner that carries a discernible human ‘finger print’. For example, heating is confined to the lower atmosphere—above the greenhouse layer temperatures are falling.

Why is this a public health issue? It is important to recognize that for human health, variability and frequency of extreme events are often more important than average conditions. On exposure to heat or cold, it is the deviation from usual or most commonly experienced temperatures that carry the greatest risk.

While humans may be able to cope with modest increases in baseline temperatures, there are physical and ecological systems of importance to health that are exposed to environmental change and may be exquisitely sensitive to temperature rise. Agriculture generally operates as an open system, directly exposed to the weather, with very few buffers against extreme events or long-term shifts in ambient conditions. Warming of 2–4 degrees C in the global average would lead to substantial falls in productivity in some parts of the world. In much of sub-Saharan and southern Africa, it has been projected that an increase of 5 degrees C in the global average would reduce the growing period for some staple crops by more than 20 per cent, threatening the coping capacity and resilience of hundreds of millions of people (Thornton et al. 2010). A small degree of ocean warming above certain threshold limits may lead to death of coral and increased rates of ciguatera (fish poisoning) (Tester et al. 2010). Mosquitoes and other disease vectors also respond acutely to small shifts in temperature and rainfall, and increases in average temperatures will increase the potential for disease transmission in some populations (Wandiga et al. 2009). (Conversely, disease risks may be reduced in areas where conditions are presently close to the upper limits of vector survival (Gething et al. 2010).)

Another mechanism by which an extra degree or two (or four) of global warming may affect human health is through displacement of populations. Projected effects of climate change include sea level rise, increased intensity of storms and floods, prolonged droughts and crop failure, all of which may cause large numbers of people to move, bringing heightened risks of poverty, conflict, and violence (see Box 2.8.2) (McMichael et al. 2012).

Observational studies of weather, climate, and health

A great deal has been written about variations in weather (day-to-day conditions) and climate (average weather over a period of decades) to health outcomes. One of the exposures most closely studied is temperature, which may be expressed in many ways, commonly as the daily average or maximum temperature, with or without an adjustment for humidity. Fig. 2.8.2 shows a pattern that is frequently observed—a U- or J-shaped relation between temperature and health outcomes (in this case, mortality excluding accidental deaths). The optimal temperature (the point at which mortality is lowest) differs from one setting to another. In the case of Haerbin, a city located in the far north of China, the number of deaths is at its lowest when the average temperature

Box 2.8.2 Too big? Or too big to ignore? The challenge of scale

Climate change is fundamentally different from most other environmental problems that public health has faced. It is a matter of scale. Climate change is a global problem, not only because the effects are widely distributed, like acid rain, or influenza epidemics, but because the underlying cause is a disruption of the planet’s homeostatic systems. The only forerunner is the depletion of high-level atmospheric ozone by chlorofluorocarbons. Climate change also moves on unprecedented timescales. For instance, the full effects of a spike in greenhouse emissions on warming of the deep ocean and associated sea-level rise may not be apparent for 5000 years or more (Stouffer 2012). This provides a serious challenge to public health scientists. In the last hundred years, the focus has shifted to finer-grained explanations of disease and injury, assisted by new technologies and greater knowledge of the mechanisms of disease. The concentration on proximal causes has brought many successes (such as the control of infectious diseases, and opportunities for specific nutritional interventions). Some have argued that there is an important lesson here, that engaging with upstream causes may be a distraction, and is unlikely to provide significant public health gains (Rothman 1998). Others maintain that a fine-grained approach, in which the unit of observation is increasingly microscopic (individual, organ, genes, and molecules) misses an important part of the public health picture (McMichael 1999). The contexts in which chemical reactions occur, microbes multiply, and individuals make their decisions is key to understanding both risk and resilience, according to this view. Mortality in the 1995 Chicago heatwave was a function of both individual-level variables (such as age and income), and the qualities of neighbourhoods. The poor and the elderly were at much greater risk during the heatwave if they lived in areas with rundown businesses, abandoned housing, and degraded public spaces (Klinenberg 2003). Climate change represents a particularly stark example of a big-picture problem, featuring extended timescales, ubiquitous exposures, and the confounding effects of human adaptation. If public health intends to grapple with the most important health problems, some contend there is no choice but to move upstream, to move from studies of the variations between individuals to studying causes on a larger scale, and to embrace and overcome the difficulties that will, inevitably, be encountered (Pearce 2011). This will very likely require refinement of established methods of public health inquiry (such as time series analysis, and ecological research designs); an understanding of climate science and meteorology; the creative use of analogues; and the application of relevant modelling methods from other disciplines (e.g. systems dynamic modelling) (Woodward 2002).

is close to 0 degrees C (Yang et al. 2007). In cities located closer to the equator, the optimal temperature tends to be higher (Fig. 2.8.2). The overall shape of the curve relating temperature to mortality remains similar, but the point of inflection on the curve moves towards the right in cities in which high temperatures are more commonly experienced (McMichael et al. 2008). This is a reminder that populations do adapt to their ecological context, physiologically and socially. What is less clear is how quickly this

Fig. 2.8.2 Average daily apparent temperature and total mortality: Santiago (33 degrees S), Sao Paulo (24 degrees S), and Mexico City (19 degrees N). Solid lines show central estimate, dashed lines the 95 per cent confidence intervals. Adjusted for particulate pollution and ozone levels.

Reproduced from Bell ML et al., Vulnerability to heat-related mortality in Latin America: a case-crossover study in Sao Paulo, Brazil, Santiago, Chile and Mexico City, Mexico, *International Journal of Epidemiology*, Volume 37, Issue 4, pp. 796–804, Copyright © The Author 2008, with permission from Oxford University Press.

adaptation can occur, if people move, or the climate changes, and what are the limits of adaptation—how much heat is tolerable?

Higher temperatures have been linked with a range of health outcomes including deaths and hospital admissions for respiratory and cardiovascular diseases. In heatwaves, which may be defined as prolonged exposure to temperatures in the top 5–10 per cent of the range for that location, the effects appear to be greater than would be expected by simply extrapolating the temperature–health outcome relationship (Anderson and Bell 2011; Rocklöv et al. 2012). Duration of heat, frequency of heatwaves, and timing (early or late in the season) all appear to modify the effects of high temperatures. It is unclear how much of the elevated mortality risk associated with low temperatures is explained by seasonal factors other than cold weather, such as outbreaks of influenza and other infections that may be linked to winter crowding, as well as conditions attributed to decreased exposure to sunlight and reduced vitamin D levels (Goldstein et al. 2011). Mortality from cardiovascular conditions, the most common cause of death in many countries, is only weakly associated with low temperatures (Ebi and Mills 2013).

There is considerable variation within populations in vulnerability to heat. Older people (70 years and over) and children are generally at greater risk. There is no consistent pattern with gender. Men were found to be at greater risk in Sao Paulo and Santiago (Bell et al. 2008); whereas a study in Brisbane, Australia reported a more marked increase in mortality risk for women than men (Huang et al. 2012). In many countries, low socioeconomic

status (SES) has been associated with increased risk of heat- and cold-related poor health, but again, this is not universal. There is, for example a greater variation by SES in heat mortality in the United States than in England, perhaps because the use of air conditioning is distributed differentially in the US but not so much in the United Kingdom (where few houses have artificial cooling and there is much less social variation) (Armstrong et al. 2011). Vulnerability is also expressed spatially (Uejio et al. 2011) reflecting the geographical distribution of individual and household characteristics (such as prevalence of chronic diseases, housing design, and poverty) and also district-level variables (urban form, quality of services). It is not just the maximum or average temperatures that affect health. Variability is important as well. In 135 United States cities, for example, the standard deviation of summer temperatures was associated with mortality of older people suffering from chronic disease, after adjustment for a wide range of risk factors including average temperature (Zanobetti et al. 2012).

As with many climate change impacts, more is known about the effects of high temperatures in high-income countries than in the developing world, although the problem is likely to be more severe in the latter, given the high temperatures that already apply in many low-latitude countries, the very large populations, often with multiple health problems, that are exposed, and the low quality of housing and urban environments. Given climate change projections, there is renewed interest in the effects of heat on the health of workers. This is especially significant in equatorial

countries where high temperatures already place severe restraints on the duration and intensity of outdoor work (Kjellstrom et al. 2013).

In 2003, Europe experienced a particularly severe heatwave, affecting France most notably. In July, a spike in temperature of 5–8 degrees C resulted in about 100 extra deaths in Paris. The following month Paris experienced almost 2 weeks of daily mean temperatures that were 10–12 degrees C above the normal level for the season. The heatwave caused about 1000 extra deaths in Paris in July, and altogether more than 30,000 deaths across the whole of Europe (Fouillet et al. 2008). These deaths were not simply events brought forward by a few days or weeks, since mortality rates after the heatwave did not fall below the long-term average until the following year.

In addition to the direct effects of extreme and variable temperatures on mortality, the effects of climate on infectious disease have long been known (see Box 2.8.3). The first textbook of tropical medicine, by Patrick Manson, was published in 1900, and was called *A Manual of the Diseases of Warm Climates* (Manson 1900). Manson wrote principally of infectious diseases but he recognized that few conditions were peculiar to the tropics. In other words, he understood that climate variables such as temperature and precipitation play an important part in, but are seldom the entire explanation for, the distribution and occurrence of disease. The mosquito-borne diseases are good examples. In warmer conditions, vectors such as *Aedes aegypti* (responsible most commonly for the transmission of dengue fever) develop more quickly from the immature stage (Tun Lin et al. 2000). In tropical countries in which temperatures vary little through the year, the transition from a time of low rainfall to the rainy season may act as a powerful climatic trigger for outbreaks of dengue (Schreiber 2001). However, other factors, such as the degree of urbanization and the quality of housing, commonly have a strong role in modifying the effect of climate on dengue risk (Wu et al. 2009).

The sensitivity of dengue to climate variations has been demonstrated on a regional scale from investigations of the ENSO in the Pacific. Every 4–6 years, approximately, the prevailing east-to-west flow of the trade winds across the Pacific weakens, ocean currents are affected, and warm water spreads from the west Pacific to the east. In the southern Pacific (including Fiji, Samoa, Tonga, the Cook Islands) the La Nina stage of ENSO, which brings warmer

Box 2.8.3 Plague and climate

Plague is caused by infection of humans with *Yersinia pestis*. The organism is established in rodent populations in parts of Asia, Africa, and the Americas, and periodically causes outbreaks of disease in local populations. The prevalence of *Yersinia* in animal hosts is climate sensitive. For example, a study of gerbils in Kazakhstan found the risk of disease was increased by warmer springs and wetter summers (Stenseth et al. 2006). An increase of 1 degree C in spring was associated with an increase of more than 50 per cent in the prevalence of animals infected with *Yersinia*. Climate also affects the abundance of rodent hosts and flea vectors, as well as the chances of humans coming into contact with the pathogen. Consequently, it is not surprising that many historical studies have shown a link between climate and plague epidemics. As one example: a study of plague in China between 1850 and 1960 found the number of cases per year was positively related to rainfall, although extremely high precipitation in the wetter parts of the country led to lower than expected plague intensity (Xu et al. 2011).

and wetter conditions to that part of the world, has been strongly associated with the number of dengue outbreaks (Fig. 2.8.3).

There are many other examples of health conditions that are sensitive to variations in climate or weather. In the south-western part of Australia, the prevalence of depression has been related to the severity of long-term drought (measured as dry-land salinity) (Speldewinde 2009). In Bangladesh the dry season is marked by increasing salinity and rising temperatures of the ground water, and it is thought these changes are linked to marked seasonal variations in the incidence of high blood pressure and eclampsia in pregnancy (precipitated by increases in sodium loading), and cholera (Xun et al. 2010).

In summary, humans have evolved to experience minimal mortality in narrow temperature ranges that are context specific. The connection between extremes of cold and heat on mortality is well established through our understanding of excess winter mortality and deaths resulting from heatwaves. In addition there are studies of specific infectious and non-infectious diseases demonstrating variation with both climate and weather.

Attribution—present impacts of climate change

In its Fourth Assessment Report, published in 2007, the IPCC concluded that ‘warming of the climate system is unequivocal’ and ‘most of the observed increase in temperatures since the mid-twentieth century is very likely due to the increase in anthropogenic greenhouse gases’ (Solomon et al. 2007). The Fifth Assessment Report confirms that we are extremely likely to be experiencing the early stages of human-induced climate change (reference to 5th assessment report WG1). In other words, according to the IPCC, we are (very likely) seeing the early stages of human-induced climate change.

As well as temperatures increasing beyond the bounds of what are regarded as natural variability, the IPCC assessment documented numerous changes in physical and biological systems that are consistent with global warming. For example, nearly two-thirds of fish species in the North Sea have shifted in latitude or depth or both, over the space of 25 years, in accord with warming of the ocean (Perry 2005). In the Alsace region of France, in association with higher summer temperatures, the potential alcohol content of Riesling grapes, at harvest, has climbed by almost 1 per cent per year (Duchene and Schneider 2005). These changes in physical and biological systems are clearly attributable to climate change. It is more difficult to attribute effects of climate change on the frequency of injury or disease, or other measures of human ill health, than on measures such as the location of fish stocks or levels of sugar in grapes. There are three reasons. The phenomenon of adaptation has been mentioned already—most human societies are well buffered against the effects of climate variability and extremes. Second, it is often difficult to distinguish effects of climate from other co-temporaneous causes of ill health (for example, the disruptive effects of migration or expanding settlements in disaster-prone locations). Third, because climate change takes place over decades, we need outcome data for the same length of time. But it is unusual, especially in the most vulnerable parts of the world, to have accurate and reliable information on health status over such long periods.

Finding early evidence of health effects attributable to climate change requires data extending over many years, in areas where the relationship between climate and health is strongest, where adaptive capacity is weak, and where there are few competing explanations (Woodward and McMichael 2001). It is a challenge to identify conditions and settings that meet all these criteria.

The story of tick-borne encephalitis (TBE) illustrates well these complexities of attribution. In the last decade of the twentieth century the vector for TBE moved northward across the Baltic and Scandinavia, in association with warming that has been most marked in winter and early spring (Lindgren 2001). The incidence of TBE surged in the early 1990s in the Baltic states, but disease trends do not fit neatly with the change in climate. There were considerable variations within the Baltic in TBE rates, and although warming has continued, TBE rates have diminished since 2000 (Sumilo et al. 2007). Clearly there are other factors that are important besides the arrival of a climate that was more favourable for transmission of the TBE virus. When the Soviet Union broke up in 1989, many collective farms ceased to operate, areas that had been used for pasture and agriculture were left untended, and these provided new habitat for rodents and deer. At the same time, during

a period of economic disruption and transition, people were more dependent than before on wild food sources, including mushrooms and small game, and as a result spent more time in the countryside. In combination these changes, climatic and non-climatic, may have increased tick abundance and boosted, for a short time, the exposure of humans to tick-borne diseases (Sumilo et al. 2007).

In public health, the accepted way around this difficulty of attribution is a risk-based approach which estimates the increase in the probability of an event occurring due to a particular exposure. No one would think inability to attribute a particular instance of lung cancer to cigarette smoking is inconsistent with a firm conviction that smoking causes the majority of such cancers in populations in which tobacco use is common. But such an approach to detection and attribution is less frequently applied in the natural and biological sciences—the disciplines that by and large are responsible for the production and assessment of much of the evidence on climate change (Parmesan et al. 2011).

Here are two examples of risk-based approaches to attribution. A study of the 2003 European heatwave concluded it was very likely (probability greater than 90 per cent) that human influences on climate had more than doubled the risk of such an extreme event (Stott 2004). Note that a relative risk of more than 2.0 means it is more likely than not that the outcome is attributable to the exposure, and this is the standard of proof that is applied in some jurisdictions to establish liability (in, for example, disputes over diseases related to exposures in the workplace). This raises the tantalizing question of who or what should be held liable, globally, for warming that raises the risk of damaging heatwaves more than twofold.

As part of the 2002 Global Burden of Disease project, the contribution of climate change up to the year 2000 was estimated, providing an overall assessment of present impacts. This followed the steps that are usually taken in a health risk assessment: choose the conditions that are thought to be sensitive to the exposure; quantify the dose–response relationship; define alternative exposure scenarios; and calculate the burden of disease attributable to the difference in exposure between what is observed and what would have applied in the counterfactual situation. The increase in average temperatures across the globe between 1961–1990 and 2000 was calculated, and applied to the population distribution worldwide in 2000. Included as outcomes were heatwave deaths from cardiovascular causes, episodes of diarrhoea (in countries with gross domestic product (GDP) per capita less than US \$6000), clinical cases of malaria and dengue, fatal injuries due to natural disasters, and the prevalence of malnutrition (Campbell-Lendrum et al. 2006). The findings are shown in Fig. 2.8.4, along with future impacts which will be discussed in the next section. Note that the direct effects (fatalities due to floods), and the impacts on vector-borne diseases, are much less than what is estimated to be the additional mortality and ill health attributable to climate-induced malnutrition.

This work rests on assumptions that are critical to the calculations and appear plausible but remain uncertain. The assumptions include: the effect of warming on disease and injury is independent of the original temperature; there are no interactions between the outcomes of climate change (e.g. malnutrition and incidence of diarrhoea); risk coefficients are valid (unconfounded) and precise, and can be generalized to all populations; climate sensitivity declines as countries become richer; and the extent of warming assigned to climate change is accurate.

Forecasting

We have demonstrated how difficult it is to attribute past and present morbidity and mortality to climate change, but future attribution presents even greater difficulties. There is no certainty about how much the climate will change in the future, or what the consequences will be, but it does seem clear that the most important risks lie ahead of us. Present-day effects of climate change on health may be miniature versions of future effects, or perhaps not: future challenges may be threshold-crossing novelties. For this reason, a great deal of effort has been applied to attempts to project future climates and the consequent impacts through modelling studies. One approach is to attempt to isolate the effect of an altered climate on specific diseases by holding all other independent variables constant. We will look at examples of this approach using several diseases known to be highly climate sensitive: diarrhoeal disease, malaria, schistosomiasis, and urinary stones. Since climate change acts as a multiplier of disadvantage, ideally studies would go further and ask: how are the 'baseline' risks likely to change in the short to medium term? This is a difficult undertaking but could, potentially, provide a more accurate description of future impacts of climate change on human health. Modelling studies that have taken this approach are less common and require methods less familiar to epidemiologists—methods that can deal with significant levels of complexity, non-linear interactions and feedback dynamically over time.

In addition to estimating the present burden of disease from climate change, the 2002 Global Burden of Disease project included estimates of deaths and disability-adjusted life years attributable to climate change in 2030 (Fig. 2.8.4). In the case of diarrhoeal disease, this was done by estimating average temperatures across the globe in 2030, at a very fine geographic scale, overlaid on an estimate of the world population distribution in 2030 (Campbell-Lendrum et al. 2006). It was assumed that the relation between temperature and incidence would not change, and that vulnerability to warming-related diarrhoeal disease would also

remain as it is currently. (Countries with a GDP per capita less than US \$6000 were treated as susceptible: countries with higher levels of GDP were assumed to be unaffected.) It was assumed also that the effect of rising temperatures is independent of the starting temperature, and that there are no effects of changes in rainfall.

In a similar vein, a study of future impacts of climate change on the 'potential transmission' of malaria in Zimbabwe attempted to isolate the effects of climate between 2000 and 2050, by assuming there would be no other changes (Ebi et al. 2005). The suitability of the climate for stable transmission of *Plasmodium falciparum* malaria was related to mean temperatures, winter minimum temperatures, and monthly rainfall, based on outputs from the MARA (Mapping Malaria Risk in Africa) project. On this basis the researchers reported that within 50 years malaria could be established in the densely populated and presently malaria-free highlands of Zimbabwe. The model used in this study was risk based (suitability varied from 0 to 1), was explicitly projecting the potential for disease, rather than predictions of disease occurrence, and set aside the question of how other influences on malaria, apart from climate, might differ in 2050 from the present day.

In China, it has been observed that the snail that harbours the parasite responsible for schistosomiasis is restricted to areas in which the average January temperatures are above freezing, and on the basis of this, and other parameters, climate change models have been applied to estimate that an additional 8 per cent of the land area of the country may be suitable for transmission of the disease in 2030 (Zhou et al. 2008). No allowance was made in this study for future changes in land use, healthcare, housing conditions, or other factors that are known to affect susceptibility to schistosomiasis.

Finally, in a less common non-communicable disease example, a study in the United States modelled the current relation between mean annual temperature and hospital admissions for stones in the urinary tract in the United States. In general, nephrolithiasis is more common in populations living in warm climates, and this trend is apparent in the United States. The authors applied projections of mean annual temperatures in the future and calculated the potential increase in hospital admissions and associated costs (Brikowski et al. 2008). Since both linear and non-linear relationships between temperature and risk fitted the present data, both forms were modelled. Projections were based on one of the IPCC's intermediate severity climate change scenarios (SRES A1B). Fig. 2.8.5 shows the projected increase in risk by 2050, using the linear model to relate prevalence to temperature. The authors calculated that the increase attributed to climate amounts to approximately 2 million additional lifetime cases.

There has been much interest in projections for dengue fever, given the rapid spread of the disease in the last 50 years, and the lack of a vaccine or effective treatment (Degallier et al. 2009). Outbreaks of dengue fever have been related to monthly average vapour pressure. Assuming no change in population susceptibility, it is therefore possible to map the potential extension of dengue in a warmer and wetter world (Hales et al. 2002). However, the relation between climate and dengue transmission is complex (Russell et al. 2009). Increasing temperatures may reduce virus incubation, extend the transmission season, and increase vector feeding rates. But mosquito mortality also increases (especially if the humidity falls). Heatwaves may increase the risk of explosive outbreaks through increased mosquito breeding, but

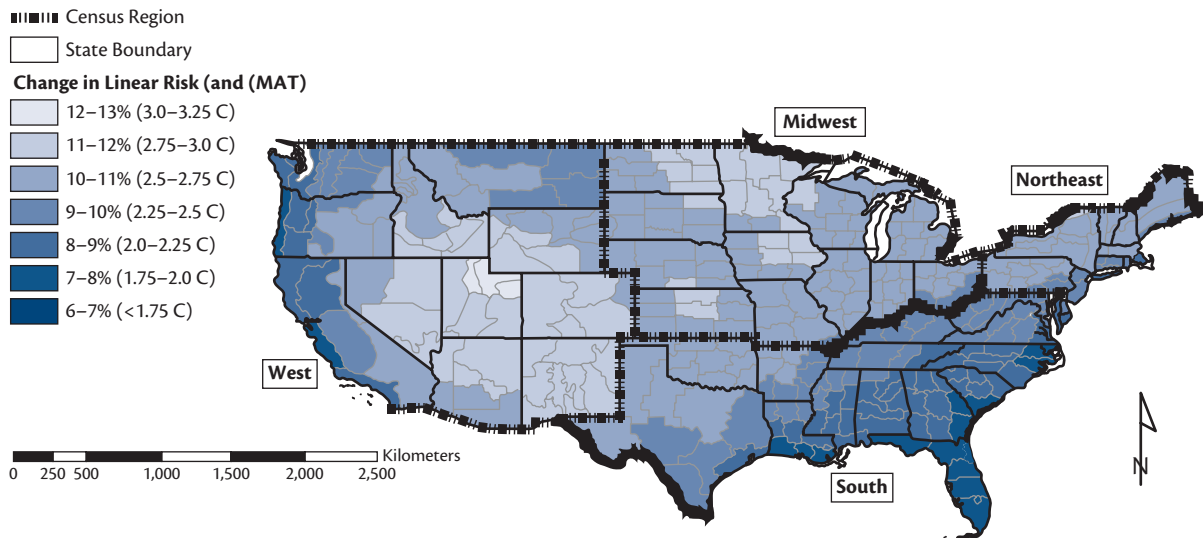

Fig. 2.8.5 Increase in mean annual temperature and risk of nephrolithiasis with the SRES A1B scenario, United States, 2050.

if populations have access to air conditioning, and spend more time indoors, there will be less exposure to the disease vector, and transmission of dengue may be inhibited. Droughts may reduce vector numbers if there are fewer free-standing and accessible bodies of water for mosquito breeding, but if instead there is widespread use of unscreened water storage, vector numbers will rise. A New Zealand study modelled future high-risk areas for dengue transmission by adding population growth, travel, and freight imports to changes in temperature and rainfall projections (De Wet et al. 2001). New Zealand is presently free of the disease and also does not host competent mosquito vectors. So projections included factors such as container traffic that might influence the risk of importing the most likely vector, *Aedes albopictus*.

Demographic projections are important, since climate change impacts will depend on the size, structure, and health status of world populations. The mid-range estimate is for the world population to increase from about 7 billion presently to around 9.5 billion by 2050, with most of the growth occurring in developing countries (Stephenson et al. 2010). The proportion of the population in older age groups is likely to increase, almost everywhere, although the average years of life remaining will change much less (Lutz et al. 2008). Mortality is projected to decline, in most countries, leading to increases in life expectancy at birth of around 5–6 years by the mid-century (World Health Organization 2011). Assuming that present trends of social and economic development continue, illness rates will also decline, and it has been estimated that the overall burden of disease (measured in disability-adjusted life years) will be reduced by about 30 per cent by 2030 (World Health Organization 2008). Child mortality is falling, worldwide, with no sign of a reduction in the rate of improvement (Rajaratnam et al. 2010). However, there are still very large differences between countries, and some countries, especially in sub-Saharan Africa, are improving slowly, if at all (World Health Organization 2011).

The emission scenarios adopted by the IPCC in its Third Assessment Report assumed that per capita incomes in developing countries would grow by about 4 per cent per year throughout

the first half of this century, considerably more than the rate observed over the last 50 years. A similar bias is apparent in the World Health Organization's (WHO) projections, in which GDP growth continues in all countries, even the worst-case scenarios (Mathers and Loncar 2006). Whether social and economic development does continue on present trajectories is of course uncertain, but is fundamental to projections of climate change (because current patterns of economic growth increase greenhouse gas emissions) and vulnerability to its effects. In turn, uncertainty about the pace of social and economic development stems, in part, from the possible effects of climate change on societies and economies. Overall, one would say, the IPCC and WHO assumptions are optimistic.

Furthermore, health is sensitive to the manner in which economic growth occurs. If development is not inclusive, then vulnerability to the effects of climate change may not improve. India, for instance, has taken great strides, economically, in the last 20 years, but the health problems of poverty persist for many people. The prevalence of child underweight and stunting fell modestly between 1992 and 2005 (from 49 per cent to 40 per cent underweight, for instance), but there was no relation, at the state level, with income growth (Subramanyam et al. 2011). Child health measured in this way advanced no faster in the richest states than the poorest.

Finally, will there be positive effects of climate change, and if so, how will they balance the negative impacts? This is not a straightforward question to answer. It is likely there will be some positive effects in the short term, but it is difficult to judge their magnitude. For instance, it is likely that modest warming will boost agricultural yields in temperate parts of the world, increasing food production in these regions. Moreover, food crops such as wheat, rice, barley, and oats, tend to grow more quickly in higher levels of CO₂. Together, these effects may reduce the risk of food shortages and under-nutrition caused by lower production in hot, low-latitude countries (Gornall et al. 2010). The balance of gains and losses will depend on whether populations at risk of food shortages can in

fact get access to the climate dividend, and the relief may be temporary: the increase in crop yields in temperate zones will almost certainly diminish as warming continues (Teixeira et al. 2011). In tropical developing countries, where food insecurity is greatest, the impact will be most severe. In sub-Saharan Africa, where the caloric intake of 60 per cent of the population is currently insufficient for an active life, 5 degrees of warming (global average) is projected to cut maize yields by 19 per cent and beans by 68 per cent (Thornton et al. 2010).

Where disease vectors and pathogens are already close to the upper temperature limit for reproduction and transmission, further warming is likely to reduce the risk of disease. In parts of equatorial Africa, for example, projected temperatures will exceed the optimal settings for both the vector and the parasite, and the potential for malaria transmission will rapidly diminish (Mordecai et al. 2012).

The effects of cold and heat on mortality have been closely studied, and shed some light on the matter of balancing gains and losses with global warming (Ebi and Mills 2013). The U- or J-shaped relation between ambient temperature and mortality suggests that warming will lead to fewer cold-related deaths, and greater heat-related mortality. But as noted already, it is unclear how many of the deaths that occur at colder times of the year are in fact due to low temperatures, rather than other phenomena that vary with season (such as infectious disease epidemics). Also, the U- or J-shaped curve is rarely symmetrical—in cooler locations, the right-hand arm of the curve (associated with heat) tends to rise more rapidly, and the opposite is true for populations living in relatively warm conditions. This means that if there is a trade-off of gains and losses with warming, the balance will depend on the initial conditions. But it is more complicated still—it is not clear whether cool-location populations will retain their (relatively greater) tolerance for cold as temperatures rise, or whether the shape of the temperature–mortality curve will change. Finally there is evidence that many populations in colder parts of the world, where the most affluent and best buffered populations in the world are located, have adapted to a large extent to cold, and the impacts of both cold spells and ambient low temperatures have much reduced over time. Consequently, the added benefits of global warming in these locations may be modest and are outweighed by the additional burden of heat-related ill health in the much larger and more vulnerable populations living in low latitudes (Kinney et al. 2012).

It is also necessary to consider the most important sources of uncertainty in projections of this kind. An analysis of the projections for diarrhoeal disease attempted to distinguish the effects of uncertainties in temperature changes and the exposure–response function (change in disease incidence per unit warming) (Kolstad and Johansson 2010). The focus in future-oriented studies tends to be on the climate modelling, given the many assumptions that have to be incorporated. However in this case it was evident that uncertainty associated with the risk coefficient (which varied almost fourfold between studies) caused more variation in the outcome than the choice of climate change model. Another study in the United States examined the effects of modelling choices on national mortality attributable to low-level ozone, in the presence of climate change (Post et al. 2012). Results varied from about 600 deaths per year avoided as a result of climate change to 2500 deaths attributable to climate change (although most models

projected increases in mortality). The most influential analytic steps were the choices of climate change scenario and air quality model. It should be noted also that the ozone studies, and many other investigations of climate impacts, have tended to project effects based on mid-range climate scenarios, when the globe is in fact tracking on a steeper trajectory for emissions, one that fits more closely with the high-range models. This highlights the issue of thresholds and tipping points—as we move further away from familiar environments and encounter more extreme exposures, it becomes less certain that present exposure–response relations will apply in the future.

There are two ways of responding to climate change: adapt to the new environment (analogous to secondary prevention), and mitigate (primary prevention—take whatever steps are needed to avoid dangerous climate change in the first place). Primary prevention is the public health ideal, but there are strong arguments for now also investing in adaptation: in particular, we are committed to the warming that will occur as a result of greenhouse gases already emitted, due to the long time-course of global carbon cycles and heat transfers. This is regardless of future emission trajectories.

Adaptation to expected climate change

The importance of adaptation is proportional to the momentum of climate change—when there are very long lag times in the climate system then interventions to reduce emissions will take a very long time to have their full effect, and in the meantime, steps must be taken to cope with changes that are, in effect, unavoidable. It has been estimated that warming of about 0.7 degrees C is already committed by the greenhouse gases that are now in the atmosphere. Also in the atmosphere are air-borne particulates that have a cooling effect, and are tending to dampen down the global warming signal. It is difficult to determine the size of this effect, but it may be as much as 0.6 degrees C of warming will result when particulate levels fall (Stern 2007). Then there is the question of future emissions, and how rapidly these will be reduced. At present, global emissions are close to 50 Gt CO₂ equivalent per year, about 14 per cent higher than the level required to hold warming to around 2 degrees C, the amount of warming that has been adopted (controversially) in international negotiations as the threshold for ‘dangerous climate change’. Moreover, total emissions continue to increase by about 2 per cent per annum (United Nations Environment Programme 2012). If emissions peaked in 2025, which would seem a relatively optimistic scenario, and then reduced by 3 per cent per year, global average surface temperatures would rise by as much as 4 degrees C by the end of this century (Parry et al. 2009). We have already discussed the way extremes of temperature are hidden within such average rises.

Given current forces driving emissions upwards, it is becoming less and less likely the world can keep to the 2-degree C target. These drivers include the population pressures identified earlier (a 50 per cent increase projected worldwide in the next 50 years) and economic development ‘catch up’: 90 per cent of the growth in emissions this century will come from states that are presently in the low- and middle-income categories. Perhaps most importantly, there continues to be a lack of leadership from the governments of most high-income countries which are responsible for 90 per cent of the emissions currently in the atmosphere.

The already locked-in climate change and the risk of mitigation failure are both compelling reasons to find options for coping with climate change impacts, particularly adaptation to increasing average and extreme temperatures, as well as resilience to storms, flooding, sea level rise, and disruption to agricultural production and distribution. Here we will examine some of the opportunities for adaptation, ranging from individual behaviours to neighbourhood interventions, to sector-wide changes. Some of the available options for adapting to climate change can also assist with climate change mitigation, or have other co-benefits for health and equity, while others may hamper efforts in these areas. We cover some examples relating to heat and storm events.

At an individual level, improving the body's physiological response to temperature extremes can assist with adaptation. Increasing physical activity and reducing obesity both have many benefits to health, including enhanced capacity to deal with heat. Clinical trials have shown that short-term endurance training increases sweat rate and peripheral blood flow and leads to more effective control of body temperature during exercise (Ichinose et al. 2009). Overweight military recruits in the United States were found to be seven times more likely to suffer heat illnesses during training than their colleagues (Bedno et al. 2010). Work of this kind indicates that public health programmes to promote physical activity, prevent unhealthy weight gain, and reduce the prevalence of obesity are likely to reduce vulnerability to heat.

Community-oriented interventions have promise, since risk factors for heat-attributable deaths tend to cluster spatially. For instance, a study in Chicago found that poverty, social isolation, lack of access to air conditioning, age, and the prevalence of diabetes were concentrated in a relatively small number of neighbourhoods (Reid et al. 2009).

Although air conditioning is an important measure for coping with high temperatures (Ostro et al. 2010), it brings vulnerability, as well as consuming large amounts of (potentially carbon-generating) electricity, and transferring heat outdoors. Artificial cooling relies on a consistent power supply, and heat-waves may trigger electricity outages due to overload (largely driven by the demands of air conditioning plants) (Anderson and Bell 2011). In these circumstances, populations accustomed to living with air conditioning may be at increased risk of ill health due to high temperatures. Cities that are built for air conditioning are often poorly designed in other ways to deal with heat (with large, exposed surfaces of glass, and minimal natural shade, for instance). Also, physiological adaptation requires some exposure to heat strain, that is, an increase in body temperature (Maloney and Forbes 2010). Populations with around-the-clock access to air conditioning are effectively isolated from heat, and therefore are less likely to develop the capacity to respond to extreme temperatures, when and if this occurs.

Cities are significantly warmer than their surrounding rural areas (the urban heat island effect) due to darkly paved surfaces and dense anthropogenic heat generation (for example, from vehicles and buildings). City-level interventions to reduce the health risks due to high temperatures will therefore be important. Designing cities to reduce the heat-island effect can also make them safer during times of high temperature. A study in Phoenix, Arizona estimated the reduction that could be made in heat-related emergency calls by an urban re-design package (Silva et al. 2010). This included changes in building and road materials to

increase heat flows, more urban green spaces, rooftop treatments, and widespread application of reflective paints. In combination, the authors estimate, these interventions could reduce inner-city temperatures sufficiently to almost halve the number of annual heat-related emergency calls. Measures at a city-level to manage high temperatures when they do occur include heat-health early warning systems, better cooling of at-risk environments (such as residential care facilities for the elderly), identifying the isolated and most vulnerable citizens, and improving the preparedness of the healthcare sector.

The contrast between more aggressive air conditioning and greater provision of green space in cities is an example of how 'business as usual' approaches can miss important opportunities (Hess 2012). On the one hand, enhancing air conditioning of all health facilities helps to protect some of the most vulnerable individuals from high temperatures, though it carries a heavy cost in power consumption. On the other hand, a radical expansion in urban green spaces may bring a range of benefits (in addition to cooling), including carbon sequestration and health benefits due to reduced air pollution, better mental health, and more opportunities for physical activity (Groenewegen et al. 2006). But these 'win win' interventions are seldom straightforward: green spaces on their own may not be sufficient to achieve health gains. A study of the 49 largest cities in the United States (Richardson et al. 2011) compared the extent of green space with all-cause mortality, adjusting for important social and demographic differences, but not for measures of urban density. The result, against expectations, was that health appeared to be worse in greener cities. The explanation is that other elements of urban renovation are critical, in combination with greening. Transport policy and land use regulation are particularly important. Otherwise, at least in the US context, the undesirable effects of urban sprawl predominate.

In France, many changes to heatwave responsiveness were made following the severe heatwave in 2003. These included public education, better emergency preparedness, and healthcare improvements. When another heatwave occurred in July 2006, the question asked was: did the country cope better this time than it did in 2003? In July 2003, the increase in daily temperatures was theoretically sufficient to increase daily mortality by about 230 per cent, according to the long-run (1975–1999) relation between temperatures and daily deaths (Fouillet et al. 2008). But a 290 per cent increase was observed, an excess of more than 15,000 deaths. In 2006, the heatwave temperatures were not as high as 3 years earlier, and it was theoretically projected to raise mortality by about 60 per cent. In fact the death rate increased by only 14 per cent (2065 excess deaths observed of about 6400 predicted). One possible explanation is that the 2003 disaster brought forward so many deaths in relatively frail individuals that the pool of susceptibles was much reduced in 2006. However, the mortality trends indicate the 4600 fewer-than-expected deaths in July 2006 were indeed evidence of effective adaptation.

Another important area for adaptation is in preparedness and resilience to severe storms and flooding. Most climate change models project an increase in the intensity of tropical storms, though it is less clear whether the frequency of storms will change. These extreme events already cause substantial loss of life and economic damage. For example, in Burma in 2008, Cyclone Nargis caused approximately 138,000 deaths and US \$10 billion damage (Fritz et al. 2009); in the United States, Hurricane Katrina

in 2005 was responsible for about a thousand deaths (Brunkard et al. 2008) and direct losses of over US \$130 billion (Field and Barros 2012). But there are also examples of countries managing the health risks of storms and cyclones. In Cuba, for example, between 1998 and 2002 the island was struck by four destructive hurricanes (category 2 or greater). Tens of thousands of homes were damaged, and hundreds of thousands of people were evacuated, but there were very few deaths (12 in all) (Thompson and Gaviria 2004).

Cuba invests heavily in traditional civil defence activities, including stockpiles of equipment, clothing, fuel, and food. There are effective storm warning systems, and good means of communicating information to the public. Other factors that contribute to resilience are high levels of literacy, provision of basic facilities in all rural areas, and a comprehensive and accessible primary healthcare system. An Oxfam analysis of disaster preparedness in Cuba found there was strong community engagement, so that populations that are threatened can be mobilized rapidly, and protection extends to all social groups, not just those with personal resources (Thompson and Gaviria 2006). In contrast, the large number of deaths associated with Hurricane Katrina was a result of serious deficiencies in the public health system, and lack of protection for the poorest and most marginalized social groups in the city (Brunkard et al. 2008).

There are other opportunities to learn from the variability in past experience of coping with climate-related health problems. For instance, enteric infections such as that caused by *Salmonella* tend to be more common at higher temperatures, but the size of the increase in disease rates for a given amount of warming varies from one site to another. A study of the five largest Australian cities found that all showed an increase in *Salmonella* notifications with monthly mean temperature, but one city stood out as following a much steeper trajectory than the others (D'Souza et al. 2004). Perhaps aspects of the food safety programmes present elsewhere are missing in this apparently particularly temperature-sensitive city.

There is no doubt that climate change acts principally as a risk multiplier. The greatest impact will occur in populations that, for other reasons, already have the worst health statistics. The World Bank, in its 2010 World Development Report concluded that 'baseline health status is the single most important determinant of both future losses, and the cost of adaptation' (World Bank 2009). It follows that adaptation must include improvements in the social determinants of health, as well as essential public health services. But is it true that this is all that is needed? In other words, is business as usual development, the package of improvements that we would want to be making anyway, sufficient preparation for climate change?

We argue that business as usual development will not be sufficient. Climate change is a special problem, and requires special responses, in addition to improvements in baseline health. To begin with, climate change is unique because of the scale on which it operates. This is a global phenomenon, and adaptation has to take account of distant as well as local effects. There is a time dimension also. Climate change accumulates and progresses, with such long lag times (apparent, for instance, in projected sea level rise) that the process must be regarded as irreversible, to a large extent. The force of change must be noted. This is not a one-off event, but a new environmental dynamic, with enormous momentum. We

are likely to be pushed to the edge of what is familiar, and beyond, leading potentially to abrupt and radical changes in Earth systems (McNeill et al. 2011). In epidemiological terms, even if the trends in exposures (rising temperatures, changing patterns of precipitation) remain the same, it may be difficult to anticipate the dose-response relationships that apply in the future, due to unforeseen tipping points, thresholds, and non-linearities. The much greater than expected impact of the 2003 European heatwave is one example of non-linear effects; another is the damage caused by unprecedentedly intense bushfires in Victoria, Australia in 2009 (Teague et al. 2010).

Climate change does not *only* multiply existing risks. It may contribute to new risks where ecosystems are pressed beyond significant thresholds. This may happen on the edges of areas affected by climate-sensitive diseases. One example is the acute illness that occurs after eating sea-foods contaminated with *Vibrio parahaemolyticus*. The organism is temperature sensitive, and until 2004 no instances of this particular food poisoning had been reported in North America above the US/Canada border. In that year there was an outbreak of cases on a cruise ship in Alaska, linked to shell-fish from a local oyster farm in Prince William Sound. On investigation, it was found that water temperatures at the farm (and the surrounding ocean) had been rising steadily for a decade, and presumably had crossed a critical boundary beyond which the organism could be sustained in local shell-fish (McLaughlin et al. 2005).

In summary, given the extent of committed warming, and the difficulty of achieving substantial reductions in emissions, the world almost certainly faces large changes in the next century. Improving baseline health status is fundamental to adaptation, but not sufficient—there are distinctive features of climate change that have to be taken into account.

Mitigation: scale, possible co-benefits, and unintended harms

There is debate about how far greenhouse gas levels in the atmosphere must fall to avoid dangerous climate change, but it is absolutely clear that big changes will be required to lower risks to a level that most governments believe is acceptable. In the past, energy revolutions have been disruptive. They have caused serious environmental damage, increased social inequalities, and shortened life expectancy. Are there paths to a low-carbon future that can achieve the opposite result—simultaneous improvements in the quality of the environment and public health? We will review the evidence for common solutions and discuss ways in which 'co-benefits' might influence policy settings for climate change.

In 2009 the World Bank reported that if the increase in emissions that has been seen in the first decade of this century continues unchecked, annual emissions of CO₂ in 2050 will be around 62 Gt, more than twice the present levels (and not counting other greenhouse gases) (World Bank 2009). If warming by the end of the century is to be contained to around 2 degrees C, then CO₂ emissions must be reduced to around 14 Gt per year in 2050, less than a quarter of business as usual projections. The later the world turns the corner on emissions, the steeper the subsequent decline will need to be. If CO₂ emissions peak in 2020, and it is assumed that climate safety amounts to a global cap of 750 Gt of carbon released between 2000 and 2050, then CO₂ emissions will need

to fall by about 9 per cent per year, a radical change in the shape of trends—from accelerating growth to steep decline (Anderson and Bows 2008). This is a tall order, and if reductions of this order of magnitude are going to be achieved, there will need to be radical changes in the way humans use energy. It will require deeper social changes than merely identifying and bringing forward renewable technologies—over the last 50 years each added unit of energy from wind, hydro, and other renewables has displaced only a quarter of a unit of energy from fossil fuel sources and has had an even smaller impact on electricity generation (York 2012). In order to meet greenhouse targets, there will need to be serious deterrents to fossil fuel use, including prices that reflect the full environmental cost.

The 2010 World Development Report talked about changes that are so large they constitute ‘an energy revolution’. Revolutions may re-orient society in a way that is beneficial, in the long run, but they tend to be disruptive and harmful, in the short term. The last energy revolution began in England in the nineteenth century and ushered in what has been in many respects a golden age of industrialization. But England, and every other country that went through the process, also experienced the ‘four Ds’—disruption, deprivation, disease, and death (Szreter 2004). In the large English cities in the 1840s, crowding, pollution, and social upheaval affected everyone, but particularly those at the bottom of the social hierarchy. For instance, life expectancy at birth fell to medieval levels, less than 30 years among the working classes (Szreter and Mooney 1998).

The challenge with climate change mitigation will be to disrupt present patterns of energy use, while avoiding the very high and inequitable social and health costs that were carried by nineteenth-century cities like Birmingham and Manchester. Early experience with alternative energy sources has not been altogether reassuring. One stark example is the encouragement of biofuels. There have been large-scale moves to use food crops for bioethanol and biodiesel, often with substantial government subsidies. (In 2009 about a quarter of all US corn was diverted to biofuel production as a result of federal intervention.) This has reduced the demand for petroleum products, but has increased competition for food staples such as soybeans, maize, and cereals—according to one analysis, increasing biofuel demand accounted for about 30 per cent of the increase in world grain prices between 2000 and 2007 (Rosegrant 2008). It remains to be seen whether second-generation biofuels, extracted from non-edible plants such as *jatropha* that are grown on marginal lands and don’t compete directly with food production, will bring the same energy benefits without the health risks.

It is possible to identify a low-risk climate path that can enhance rather than worsen health and equity. One easy example is provided by the link between short-lived climate pollutants and air quality. Emissions of black carbon particles, the precursors of low-level ozone, and methane, all of which have stronger heat-trapping properties than CO₂ on a weight-for-weight basis, have local toxic effects, and pass through the atmosphere relatively quickly. Black carbon or soot is the second most important greenhouse forcing agent, after CO₂. It acts by absorbing sunlight and darkening ice and snow, and remains in the atmosphere for about 7–10 days, on average (Kerr 2013). Typically black carbon is emitted as part of a complex mixture, including other particles that tend to be cooling (as a result of reflecting sunlight). The ratio

of black carbon to other organic material (and hence the warming potential) varies depending on the source (tending to be high in diesel fumes and smoke from cook stoves; low with forest fires).

The United Nations Environment Programme estimated what could be achieved by widespread application of measures that are proven to reduce black carbon and methane (United Nations Environment Programme 2011). These measures include particle filters for disease engines, clean burning biomass cook stoves, and bans on the open field burning of agricultural waste. Assuming full implementation by 2030, the effects compared with ‘business as usual’ emissions amounted to saving 0.5 degrees C of warming in 2050, while the reduction in local pollution would save about 50 million tons per year of lost crop yields, and avoid about 2.5 million premature deaths worldwide.

Transport and housing are two sectors where health co-benefits can be achieved, but there might also be adverse consequences for health if interventions are not carefully thought through. One example is the health and energy efficiency benefits of home insulation and efficient heating. In New Zealand, although the climate is moderate, many homes are relatively cold and damp owing to a lack of insulation, ineffective heating, and poor building design. A randomized community trial tested the effect of home insulation on indoor temperatures, energy consumption, and respiratory health (Howden-Chapman et al. 2007). Insulated homes were found to be warmer, drier, used 20 per cent less electricity than the control homes, and children in them were sick less frequently (Table 2.8.1). The findings led subsequently to a national roll-out of insulation subsidies and installation.

However, alterations to improve energy efficiency may increase health risks. For example, there is a balance in houses between airtightness and ventilation that provides for efficient warming while allowing for adequate air flow to reduce indoor air pollution, and prevent moisture from reaching levels conducive to mould growth (Davies and Oreszczyn 2011).

In many countries, emissions from the transport sector are growing more rapidly than those from any other sector. Yet there are many opportunities in transport policy to simultaneously cut carbon and improve health. This is particularly so in cities that are currently highly car-dependent. For example, in New Zealand about 80 per cent of travel is by private car, and yet many vehicle trips, in

Table 2.8.1 Outcomes of a randomized trial of insulation in 1350 New Zealand households. All households included one or more children with asthma

	Outcome
Average bedroom temperature in winter	Warmer by 0.5 degrees
Relative humidity in bedroom	Reduced by 2.3%
Energy consumption	81% of controls
Self-reported wheeze	OR 0.57 (0.47–0.70)
Days off school	OR 0.49 (0.31–0.80)
Visits to general practitioner	OR 0.73 (0.52–0.87)

OR, odds ratio.

Source: data from Howden-Chapman P et al., Effect of insulating existing houses on health inequality: cluster randomised study in the community, *British Medical Journal*, Volume 3, Issue 334, pp. 460, Copyright © 2007, DOI: 10.1136/bmj.39070.573032.80.

the city, cover very short distances. In the New Zealand Household Travel Survey 2003–2006, it was reported that about three-quarters of car trips in urban areas were 7 km or less, and almost a third (31 per cent) were 2 km or less (Lindsay et al. 2011). Shifting 5 per cent of those short trips (7 km or less) from cars to bicycles would, it was estimated, save 22 million litres of fuel per year, avoid six deaths a year from air pollution, and as a result of promoting physical activity, postpone a further 116 deaths a year from chronic diseases such as stroke, diabetes, and heart disease (Lindsay et al. 2011). If no changes were made to the road system, the additional cycle traffic might lead to an extra five deaths from crash injuries, but overall, it was estimated that the health benefits of a 5 per cent mode shift would outweigh the costs of injury by more than ten to one.

A similar modelling exercise was undertaken in Delhi, India, comparing the health effects of different mitigation strategies

(Woodcock et al. 2009). The city has set targets for greenhouse gas emission reduction, and this could be achieved by increasing the numbers of low-carbon vehicles, encouraging more active transport (walking and cycling), or a combination. The low-carbon vehicle option would avoid premature deaths and illness, mainly as a result of reduced air pollution in the city, but it was estimated these co-benefits were roughly ten times less than what could be achieved by the ‘active transport’ or ‘combined’ strategies.

In summary, global greenhouse gas emissions need to be reduced by about 60 per cent by 2050 to provide a reasonable chance of holding warming by the end of the century to 2 degrees C or less. Radical mitigation of this kind might be seriously health damaging. But there are opportunities for co-benefits: well-chosen interventions could produce health gains (early), as well as long-term climate security. See Box 2.8.4.

Box 2.8.4 Answers to the carbon IQ quiz

1. Without greenhouse gases, the temperature at the Earth’s surface would be below freezing (about –15 degrees C). The global average is instead about +15 degrees C. The answer is A.
2. Climate is long-range weather, over a timescale of decades. The British Meteorological Office, for example, uses 30 years as the averaging period, though in some recent assessments 20 years of weather has been considered long enough to define a climate. The answer is C.
3. C is closest to the mark: today’s choices about the level of emissions will have long-term consequences (Stouffer 2012). AR4 says ‘about 50 per cent of a CO₂ increase will be removed from the atmosphere within 30 years, and a further 30 per cent will be removed within a few centuries. The remaining 20 per cent may stay in the atmosphere for many thousands of years’ (Solomon et al. 2007). There are many caveats, because the various processes that soak up carbon work at different speeds, and on a large scale, the lifetime of CO₂ depends on the amount emitted, and the rate of emission. But as a rough guide, about 40 per cent is likely to be still in the atmosphere after 100 years, and just over 20 per cent after 1000 years.
4. Combustion of biomass releases a complex soup of pollutants, and reactions in the atmosphere generate ‘secondary’ agents such as ozone and other photochemical oxidants. The effects on climate are complex. Black carbon absorbs heat; sulphur aerosols have a reflective (cooling) effect. Because these agents are short-lived (remaining in the atmosphere for days or weeks), the impact is local/regional. Deposition of soot on ice causes increased absorption of solar energy, and accelerated melt. The answer is E.
5. The oceans absorb 80–90 per cent of the solar energy that is trapped by greenhouse gases. Additional amounts of heat go toward melting glaciers and sea ice, as well as warming the land and parts of the atmosphere. Only a tiny fraction warms the air at the planet’s surface.
6. According to the British Meteorological Office, 1998 still holds the record, and 2010 was the second warmest. In the United States, NASA report that 2010 was equal warmest (tied with 2005): the answer varies a little depending on which weather stations are included. Some have argued that the answer is 1260 (the period of the medieval warming)—this is definitely not true (NASA n.d.).
7. Laos emits about 0.2 tons CO₂ per head (Carbon Dioxide Information Analysis Center n.d.). A 747 jet emits about 100 g of CO₂ per passenger kilometre (Carbon Independent n.d.). Singapore to Rome return is roughly 10,000 km, which amounts to about 1 ton CO₂ per passenger, based solely on the fuel consumed during the flight. Note that this does not allow for the greater warming effect of CO₂ released high in the atmosphere, nor the embedded fossil fuel costs of aviation, which include those incurred in building jets, running airports and training staff. But on this basis the solution is 0.2 and the best answer is D.
8. A cyclist would travel 570 km on a litre of comparably energy dense food, which is 0.2 L/100 km (Wilson 2004). But this refers to a racing cyclist moving at 30 kph. Note that wind resistance falls away rapidly as speed drops—less than half the energy would be required for travel at an average of 20 kph (which means no more than 100 mL of oil-equivalent per 100 km).
9. George H.W. Bush, made this commitment at the Rio Summit in 1992, after signing the UN Framework Convention on Climate Change. In the subsequent 20 years Republican leaders have shifted their ground, and increasingly they have denied that climate change is a serious threat (Oreskes and Conway 2010).
10. There were about a thousand deaths caused by Katrina: there were typically four or five deaths in Cuba from hurricanes of similar severity (categories 2–4) between 1998 and 2002 (Thompson and Gavrira 2004). On the whole, wealthy countries are less seriously affected by climate extremes, but this is not always the case, which points to some lessons, possibly, for adaptation to climate change.

Conclusion

Climate change is a new kind of environmental problem—the scale of the phenomenon dwarfs the issues that public health workers have encountered previously. Its effects on health will result, mainly, from exacerbating disease and injury from familiar causes. Understanding how multiple variables will interact in the future to diminish or magnify the effects of climate change on health requires methods not currently familiar in public health. Complex models are needed that can incorporate non-linear interactions, feedbacks and tipping points dynamically over time.

Climate change is undoubtedly an issue of health and social equity—those at greatest risk already carry a heavy load of disadvantage, and have contributed little to the CO₂ that now sits in the atmosphere. This means that many of the impacts can be avoided, or reduced in magnitude, by providing basic health improvements to the world's poor populations.

Targeted adaptation efforts, such as early warning systems and good disaster management, are necessary also: there is plenty of evidence that high-income countries are not immune from the effects on health of climate variability. But the world is not making rapid progress on either poverty reduction or targeted adaptation, so we expect the public health dimensions of climate change to become more prominent in the next few decades. In the medium to longer term (2050 and beyond), unless there are radical reductions in emissions beforehand, it is possible the average temperature of the globe will rise by more than 4 degrees C over the pre-industrial baseline. If this happens, impacts of climate change may overwhelm all efforts at adaptation. For this reason, the response to climate change must be two-pronged—coping with adverse effects of rising temperatures and changing patterns of rainfall, and at the same time, finding ways of slashing emissions and reducing levels of climate active pollutants in the atmosphere. On the positive side, well-chosen adaptation and mitigation measures may achieve substantial health gains. Strengthening the place of public health in multidisciplinary decision-making about climate change can assist with identifying low-risk climate paths that enhance rather than worsen health and equity.

Behavioural determinants of health and disease

Lawrence W. Green, Robert A. Hiatt,
and Kristin S. Hoefft

Introduction to behavioural determinants of health and disease

Lifestyle is widely implicated in disease incidence and prevalence. That behaviour is associated with health and disease has never been in doubt. Indeed, the tendency to blame sinful, negligent, indulgent, ignorant, reckless, slothful, or selfish behaviour for health problems has too often placed undue emphasis on individual responsibility and culpability when the solution to health problems of populations demanded attention to the social and physical environment. But no matter how behaviour is framed or moralized in relation to its causes, it remains an inescapable variable in the pathway between ultimate upstream aetiologies and the incidence or prevalence of most diseases and health conditions downstream. Approaches to public health have sought throughout the history of civilization to: (1) control or cajole the health-related behaviour of individuals, (2) protect individuals from the behaviour of others, and (3) mobilize the behaviour of groups to influence health-related policies, organizations, and social or physical environments.

This chapter reviews ways in which behaviour relates to the spectrum of health and disease determinants, from environmental to genetic, in shaping health outcomes. It builds on the previous chapters in recognizing the powerful influence of socioeconomic and cultural factors, especially poverty and discrimination, in influencing both behaviour and health. Many commentaries in the past four decades have attempted to correct the overemphasis on behavioural determinants of health by discounting and sometimes disparaging any focus on individual behaviour or personal responsibility in disease prevention and health promotion, often referring to it as ‘victim blaming’ (e.g. Crawford 1977), and on another side, ‘scapegoating’ people with health problems as the cause of rising costs of healthcare (e.g. Minkler 1983). This chapter seeks a middle ground, building on the growing understanding of the ecological and cultural context of the behaviour–health relationship. It seeks to integrate that knowledge in an approach to public health that acknowledges the reciprocal determinism of behavioural, environmental, and biological determinants rather than minimizing the importance of behaviour in these complex interactions. This is consistent with a concept of ‘behavioural justice’ that Adler

and Stewart (2009, p. 49) refer to as a ‘principle that individuals are responsible for engaging in health-promoting behaviors but should be held accountable only when they have adequate resources to do so. This perspective maintains both individuals’ control and accountability for behaviors and society’s responsibility to provide health-promoting environments’.

The shifting role of behaviour as a determinant of health and disease

Simple, discrete behaviours account for many of the infections and injuries of the past. Today’s growing chronic disease burden relates more to complex behaviours, sometimes referred to as ‘lifestyle’. We use the term ‘complex behaviour’ to refer to combinations of interrelated practices and their environmental contexts, reflecting patterns of living influenced by the family and social history of individuals and communities, their environmental and socioeconomic circumstances, and their exposure to cultures and communications. We know that discrete behaviours can be influenced directly by health education targeted at individuals and groups. Complex behaviour, however, changes more slowly and usually requires some combination of educational, organizational, economic, and environmental interventions in support of changes in both behaviour and conditions of living. This combination of strategies has defined health promotion and public health programmes addressing complex behaviour change through combined efforts to predispose, enable, and reinforce the behaviours (Green and Kreuter 2005; Smith et al. 2006; Swan et al. 2012). The predisposing interventions are directed particularly at the individual, but the enabling and reinforcing interventions are directed at policies in support of, and environments in which, predisposed individuals would seek to enact and maintain the behaviour.

Obesity and HIV/AIDS present two obvious contemporary examples of health-related conditions and diseases awaiting technological solutions, for which behaviour, in the meantime, is a necessary route of intervention and change. Virtually every public health breakthrough has had a behavioural change process that served the public until the technology was at hand. Then, behavioural change processes were needed to diffuse, adapt, and apply the new technology to varying cultural and social circumstances.

For example, unless and until an obesity prevention vaccine or HIV vaccine is developed, society must depend on behavioural preventive measures to curb the spread of obesity and AIDS. These include, of course, policies, environmental changes, and health educational programmes that support behavioural changes.

Much of the early success in controlling HIV infections through change in sexual practices (especially use of condoms) among men in urban gay communities appears to have been in response to health education programmes (Petrov 1990). Reviews also show increases in the use of clean needles for at least 15 years among intravenous drug users (e.g. Wodak 2006), which has required a combination of policy and educational interventions to make clean needles accessible and more acceptable than the culture of needle sharing. Evidence that health education leads to the regular use of condoms among sexually active adolescents, however, has not held up consistently (Cervantes et al. 2011; Klein et al. 2011). The parallel lessons from the success of tobacco control programmes also point to the need for combined policy, regulatory, organizational, environmental, and educational interventions to influence population changes in tobacco consumption (Institute of Medicine 2003; Eriksen et al. 2007). Many of the same types of interventions are under consideration and evaluation for obesity control (Mercer et al. 2005; Institute of Medicine 2010, 2012).

Specific behaviours and health—the causal links

Some behaviour clearly increases the risk of developing disease and can be considered a proximal cause of disease, such as hygienic practices that expose one to infections. Other behaviours correlate with and precede better health, increased longevity, and decreased disease risk, but their causal link is more tenuous, variable, delayed, cumulative, or indirect, warranting their inclusion with more distal determinants, such as development of dietary and physical activity patterns. Examining the correlations between specific behavioural and social patterns and indicators of health and disease status provides the foundation for assessing behavioural factors as population health determinants (Evans et al. 1994). Examining the covariation of these relationships with other characteristics of the populations and their environmental circumstances helps put behaviour into its ecological, social, and cultural context (Institute of Medicine 2010, 2012).

The causal link is relatively easy to establish for single-agent communicable or infectious diseases. Evidence from observational epidemiological studies, human experimental trials, and animal models, together with clear mechanisms of biological action, lead one to conclude that many behaviours are, in fact, contributing causes (causal risk factors) of specific diseases. Again, the easiest examples of clear causal linkages are those established for single-action behaviours such as ingesting a contaminated food, getting an immunization that confers lifetime immunity, or taking a one-dose medication that leads to rapidly improved symptoms. As the number of booster shots required for immunization or doses required for cure increases, for example, the behaviour becomes more complex, requiring repetition or timing, and the causal linkage more difficult to unravel among the biomedical agent, the behaviour, and all the other events and circumstances that might have intervened and influenced the person's exposure, susceptibility, and outcome along the way.

Complex behaviours and health—the synergistic causal pathways

More difficult still are causal attributions and allocations for long-term behavioural patterns that are not under medical supervision and relate to multiple-cause chronic diseases and conditions (Glass and McAtee 2006; Krieger 1984). We present three examples of evidence supporting causal links between behaviours and coronary heart disease: smoking, diet, and physical inactivity. These three examples illustrate that even in the absence of direct experimental evidence in human beings, strong evidence of other types can be combined for the steps in a causal chain from behaviour through physiological effects to disease or health. In addition, the synergistic effects of two or more behaviours on health outcomes have been established.

A plausible biological model of the relationship between smoking behaviour and coronary heart disease has been available for decades (Dawber 1960). Observational epidemiological studies—including within- and between-population designs, case-control, and prospective designs—produced strong and consistent measures of association, the hypothesized temporal sequence, and dose-response relationships in subsequent decades (Stamler 2005). Additional randomized trials have included smoking cessation programmes that provide experimental evidence for smoking as a cause of coronary heart disease. Although the overall results of the Multiple Risk Factor Intervention Trial (MRFIT) in the United States were disappointing, in both MRFIT (Ockene et al. 1990) and the British trial on the effect of smoking reduction (Rose and Colwell 1992), cessation interventions showed decreases in coronary heart disease mortality respectively of 13 per cent after 20 years and 12 per cent after 10.5 years. In addition, when smokers at baseline from the experimental and control groups were pooled, quitters had a significant decrease in their risk of mortality from coronary heart disease compared with non-quitters (Ockene et al. 1990).

On the dietary front, evidence that saturated fat and cholesterol consumption behaviour contributes to coronary heart disease came first from ecological studies showing a correlation between dietary patterns and serum cholesterol levels (Keys et al. 1958), and later dietary fat consumption levels, and the corresponding geographical coronary heart disease incidence rates and mortality (Keys 1970). A 30-year follow-up of the Framingham cohort samples showed that high levels of serum cholesterol predicted the risk of coronary heart disease development (Anderson et al. 1987). In a meta-analysis of 27 trials, Mensink and Katan (1992) found that changes in dietary saturated fat and cholesterol led to changes in serum cholesterol. In the Helsinki Heart Study, Frick et al. (1987) showed that interventions to lower serum cholesterol levels decreased the occurrence of coronary heart disease. A definitive demonstration of the diet-heart hypothesis by a true experimental study might never occur because of the large sample size required, the sustained differential changes needed between intervention and control groups, and the long-term follow-up required for such a trial. The strong evidence for each step in a causal chain from diet to coronary heart disease and mortality, however, led to major national and international recommendations that diet be a first-line approach to reduce blood cholesterol to prevent disease, and more urgently today in the face of the global obesity epidemic (e.g. WHO 1990, 2000; Health Canada 2003; National Heart,

Lung, and Blood Institute 2004; Institute of Medicine 2005, 2012; US Department of Health and Human Services 2011).

Physical inactivity as a risk factor for coronary heart disease is the third example. Evidence that physical inactivity contributes to coronary heart disease came from studies of the biological effects of exercise on cardiovascular physiology, observational epidemiological studies, and randomized controlled trials of physical activity and physiological coronary heart disease risk factors, such as high blood pressure, obesity, and diabetes. The biological effects of exercise training to enhance cardiovascular health were well established by the 1980s (McArdle et al. 1986). Epidemiological evidence continues to show consistent and relatively strong associations, the hypothesized temporal sequence, and a dose–response relationship between physical activity and coronary heart disease (Ahmed et al. 2012). Observational epidemiological and randomized controlled trials demonstrated the beneficial effects of physical activity on blood pressure (Arroll and Beaglehole 1992) and on blood lipids and lipoproteins (Lokey and Tran 1989), which have, in turn, been causally linked with subsequent coronary heart disease. The combination of these sources of evidence for each of the steps in a causal chain provides a plausible model for the sequence.

Some of the immediate causal risk factors are not themselves behaviours, but have determinants that are behaviours. In these cases, the behavioural determinants can be regarded as indirect risk factors that act earlier in the causal pathway. For example, a combination of overeating and sedentary behaviour produce high caloric intake and low energy output, which together mediate the behavioural determinants of obesity. Obesity, in turn, is a physiological risk factor for cardiovascular diseases (CVD) and type 2 diabetes (Institute of Medicine 2005).

Behaviour also contributes to the prognosis of diseases at each stage where the screening, diagnosis, or the compliance with prescribed regimens of treatment or self-care affects outcomes. For example, the prognosis of breast cancer depends on the stage of disease at which the person obtains screening, diagnosis, and medical care. The prognosis for type 1 (insulin-dependent) diabetes depends on the patient's compliance with his or her insulin prescriptions. Because behaviour is so central to disease outcomes, a large literature on patient education and patient compliance with medical regimens has been catalogued and subjected to meta-analyses with regularity (e.g. Mullen et al. 1985; US Preventive Services Task Force 1989 and continuously updated on <http://www.ahrq.gov/clinic/uspstfix.htm>).

Behavioural risk factors in population health

The causal pathways by which behaviour can influence health (or its negative manifestations) can be broadly classified as direct (as shown by arrow 1 in Fig. 2.9.1) and indirect, where the indirect pathways (arrows 2 and 3 in Fig. 2.9.1) are largely mediated through the environment or through healthcare organization and personnel. These three determinants of health—behaviour, environment, and healthcare organization—in addition to human biology, were cast as the 'Health Field Concept' as part of the Lalonde Report on the Health of Canadians (Canada 1974), which many credit with having launched or at least facilitated the health promotion, health determinants and population health movements in public health (cf. Green and Allegrante 2011). The third indirect pathway

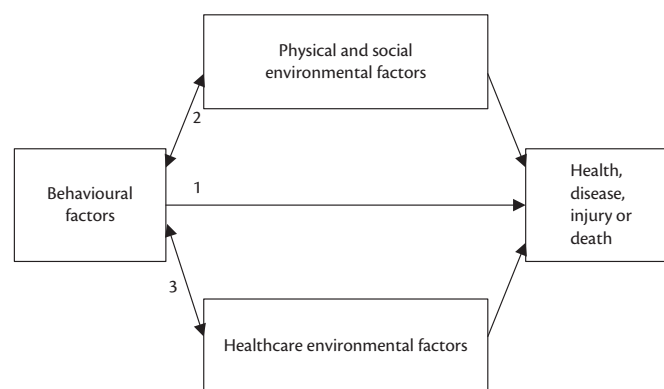

Fig. 2.9.1 Three pathways for behavioural influence on health, disease, injury, or death.

could be drawn through genetics, the main pathway by which individuals can make some reproductive decisions independent of the medical care system, but such non-medically mediated decisions are largely mediated by the social environment. Fig. 2.9.1 is hardly a full representation of the three sets of variables (behaviour, environment, healthcare organization), much less the genetic interactions, insofar as there is much reciprocal determinism between behaviour and each of the various environments, as well as with genetics. These environmental influences on behaviour will be examined in the next section, and behaviour's influence on the environment in a later section.

Behaviour itself as a risk factor for disease

The direct pathway suggested by arrow 1 in Fig. 2.9.1 includes the broad array of actions people take, consciously or unconsciously, that can have an immediate or cumulative effect on their health status. The effect on health may be intended (health-directed) or unintended (health-related), but the behaviour is nevertheless direct in its effect. The most dramatic of these are the violent injury-causing actions people may take behind the wheel of an automobile, with weapons, or unintentionally with the careless use of tools or toxic substances or merely walking absent-mindedly on a slippery or cluttered surface. Less dramatic, but no less lethal, are the cumulative little actions people take each time they light a cigarette, imbibe or inject an addictive or mind-altering substance, or neglect physical activity or healthful foods.

Table 2.9.1 lists the nine leading causes of death in most of the more developed countries, as reflected here by the United States, and relates those to the risk factors for each in column 2, which McGinnis and Foege (1993, 2004) and Mokdad et al. (2004) refer to as the 'actual causes of death'. Colditz (2001) has noted that more than half of all cancer is a consequence of behaviour, much of which is embedded in culture. Most of the risk factors in Table 2.9.1 are themselves behaviours. Those that are not behaviours themselves—such as high serum cholesterol, obesity, hypertension, and diabetes mellitus—are the physiological consequence, in large part, of behaviours. The behavioural determinants of risk factors in column 3 present some of the most challenging targets for public health intervention, because they require decreasing behaviours that are perceived as pleasurable (e.g. types of food, sedentary entertainment, casual or spontaneous sexual encounters) and increasing behaviours perceived as boring, painful, or

inconvenient (e.g. less sugary or salty foods, more strenuous or frequent physical activity, use of condoms). Their challenges are compounded by the fact that most of the instances of these behavioural determinants of risk can be carried out very privately with limited opportunity for monitoring, enforcement or social influence.

Tobacco consumption alone accounts for a large proportion of deaths in developed countries, implicated as a direct risk factor in all five of the leading causes of death shown in Table 2.9.1. At least one of the three main behavioural risk factors—smoking, dietary practices, and alcohol use—is causally related to each of the nine leading causes of death shown in Table 2.9.1. Active smoking has been established as a risk factor for coronary heart disease, diabetes, stroke, and adverse pregnancy outcomes, such as low birth weight, premature rupture of membranes, and abruption placentae (US Department of Health and Human Services 2004). As examples of how the behaviour of some individuals can influence the health of others, passive smoking (i.e. exposure to environmental

tobacco smoke) has been related to lung cancer and other respiratory diseases, as an independent risk factor for coronary heart disease, and exposure to environmental tobacco smoke in the home has been associated with asthma, other respiratory conditions, and with ear infections in infants and children (US Department of Health and Human Services 2006). Although still controversial, the California Environmental Protection Agency (2005) has concluded from its reviews that passive smoking is also a risk factor for breast cancer. This has been supported in a review of studies in Japan (Iwasaki and Tsugane 2011) and by the Canadian Expert Panel on Tobacco Smoke and Breast Cancer (Johnson et al. 2011).

As noted in previous chapters, the causes of death in developing countries differ markedly from the patterns reflected in Table 2.9.1, although the demographic profiles are converging. World Health Organization (WHO) estimates of the four leading causes of death for the developing countries have been respiratory diseases, infectious and parasitic diseases, CVD, and perinatal mortality. As tobacco use has increased and problems of macro-nutrients have

Table 2.9.1 Nine leading causes of death (United States 2003), their generally accepted risk factors, and their behavioural determinants

Causes of death (age-adjusted death rates in the United States per 100,000 population)	Selected risk factors	Behavioural determinants of risk factors
Diseases of the heart (232.3)	Tobacco smoke	Smoking
	Sedentary living	Physical inactivity
	High serum cholesterol	High-fat diet
	Obesity, diabetes mellitus	High-calorie diet, physical inactivity
	Hypertension	High-salt diet
Malignant neoplasms (190.1)	Smoking	Smoking
	Low-fibre diet	Low-fibre diet
	Physical inactivity	Physical inactivity
	Sexually transmitted diseases	Sexual behaviours
Cerebrovascular diseases (53.5)	Hypertension	High-salt diet
	Atherosclerosis	High-fat diet
	Smoking	Smoking
Chronic obstructive pulmonary disease (43.3)	Smoking	Smoking
Unintentional injuries, traffic-related (37.3)	Alcohol abuse	Alcohol use before or while driving
	No seat belt engaged	Seat belt non-use
	Unsafe driving	Behavioural distractions (e.g. smoking, texting) while driving; speeding
	Drug abuse	Drug use before or while driving
Diabetes mellitus (25.3)	Obesity	High-calorie diet, physical inactivity
Pneumonia and influenza (22.0)	Immunization status	Failure to obtain immunization
	Malnutrition	Diet
Suicide (10.8)	High blood-alcohol abuse	Alcohol use
	Handgun use	Handgun possession
	Drug abuse	Drug use
Chronic liver disease and cirrhosis (9.3)	Alcohol abuse	Alcohol use

Source: data from National Center for Health Statistics, *Health, United States, 2006 with Chartbook on Trends in the Health of Americans*, Center for Disease Control, p. 179, 2006, available from <http://www.cdc.gov/nchs/data/hus/06.pdf>. Death data from Mokdad et al., Actual causes of death in the United States, 2000, *Journal of the American Medical Association*, Volume 291, Number 1238, Copyright © 2000 American Medical Association.

replaced some of the micro-nutrient problems in those countries, other chronic diseases, in addition to CVD, have increased. By 2020, according to WHO (1998) estimates, the tobacco epidemic is expected to kill more people than any single disease. Because it is a known probable determinant of at least 25 diseases, and the most important determinant of some of the leading causes of death, tobacco use will cause nearly 18 per cent of all deaths in developed countries and 11 per cent in developing countries. This alone warrants the concerted global attention to this behaviour that has been proposed by the Framework Convention on Tobacco Control.

Behaviour as a determinant of other risk factors

Besides the cumulative effect of behaviours on physiological risk factors, such as the energy balance between calorie intake and physical activity producing weight gain, obesity, and hypertension, many of the health consequences of behaviour are secondary to their impact on the immediate environment. Individuals are not merely the passive victims of the environments they inhabit or traverse. They are agents of change in those environments, and their ability to alter or control environmental threats to their own health increases with technological innovations. The growing capacity of individuals and groups to alter their environments through technological means, such as transport, also produces negative consequences for their health. Hence, health promotion and health protection have emphasized mobilizing individuals and groups to undertake personal conservation behaviours and collective actions to support policy changes and regulatory initiatives in support of more healthful environments.

Among the most striking differences in health between the developed and the developing countries are the perinatal–juvenile mortality rates. In their analysis of 66 countries, Hertz et al. (1994) found the three most important predictors of infant mortality rates to be percentage of households without sanitation, illiteracy rate, and the percentage of households without safe water. The major public health goals in developing nations have related to the provision of immunization, access to a sufficient supply of clean water, and the installation of proper sanitation facilities (WHO 1981). But the more recent Millennium Development Goals (MDGs) aimed to cut global poverty by half by the year 2015, with three goals focused directly on health, covering maternal mortality, infant mortality, HIV/AIDS, malaria, and tuberculosis.

These environmental and age-specific or disease-specific health measures, however, achieve their intended health goals only to the extent that an informed population accepts and uses them properly. A report by the World Bank (1993) suggested that the single most important public health policy for developing countries lies in the improvement of the education of young girls. Better educated women have fewer children, who tend to be healthier and, in turn, better educated and able to respond to the technological advances offered by such environmental measures. They also become a better informed electorate to demand and support healthful policies for the installation of such facilities. In short, behaviour remains a critical mediator of the relationships between environmental measures and health outcomes, as well as the relationship between the health needs and the political actions to create the environmental changes.

The behaviour–policy link in the causal chains becomes more important as the chronic diseases creep into the developing

countries. Inspection of the recent trends in the richest of the developing countries provides evidence that improvement of the socioeconomic condition is accompanied by a shift in mortality towards the chronic diseases and their behavioural risk factors reviewed earlier. In Mexico, for example, as early as 1991, infectious and parasitic diseases were only the fourth leading cause of death, following diseases of the heart, malignant neoplasms, and unintentional injuries. Developing countries are now the primary target for market expansion for the multinational tobacco companies, with convenience food companies close behind them. Behaviour will be an issue both in personally resisting the temptations offered by these industries and in collective action to restrain their advertising, promotion, ingredients, and location.

Behaviour as a consequence of cognitions, environments, and genetics

Notwithstanding the implied simplicity of identifying a few behaviours that account for the majority of deaths in developed countries, those and other behaviours are highly complex, value-laden, and over-determined. Most behavioural risk factors and healthcare behaviours as well, are the product of a variety of component behaviours, tasks, skills, or actions. For example, food consumption confronts most people with a chain of related behaviours that includes procuring and selecting food, planning menus or selecting from a menu, preparing or ordering foods, and eating with literally hundreds of food-related choices, including where to shop or eat, what to purchase or prepare, how to season food, and with whom to eat (Simons-Morton et al. 1986). One can identify similar chains of component behavioural choices for each of the other health behaviours identified in Table 2.9.1.

Not only are the behaviours complex, but each behaviour has numerous influences or determinants. Factors that influence behaviours can be grouped into three major categories (Green and Kreuter 2005; with adaptation from Andersen 1969): predisposing, enabling, and reinforcing, as shown in Fig. 2.9.2. Both positive and negative behaviours are predisposed, enabled, and reinforced by forces in the culture and the environment. This broad categorization has proved useful in public health programme planning (with more than 1000 published applications, see <http://lgreen.net/bibliog.htm> for bibliography) because it groups the determinants of behaviour according to the major strategies used in public health to influence them. *Direct communications* through mass media, schools, worksites, other organizations, and through patient counselling in health clinics are used to influence the predisposing factors. *Indirect communications* through parents, teachers, clergy, community leaders, employers, peers, and others are used to strengthen the reinforcing factors with organizational rewards or social-normative influence. *Community organization, political activation, and training* strengthen the enabling factors by mobilizing and moving resources, policies, and building skills and capacities.

Predisposing factors

Predisposing factors reside in the individual and include attitudes, values, beliefs, and perceptions of need, but these are shaped over time by cultural and social exposures, which produce reinforcing factors (see later). Predisposing factors are those antecedents to behaviour that provide the rationale, motivation, or drive for an

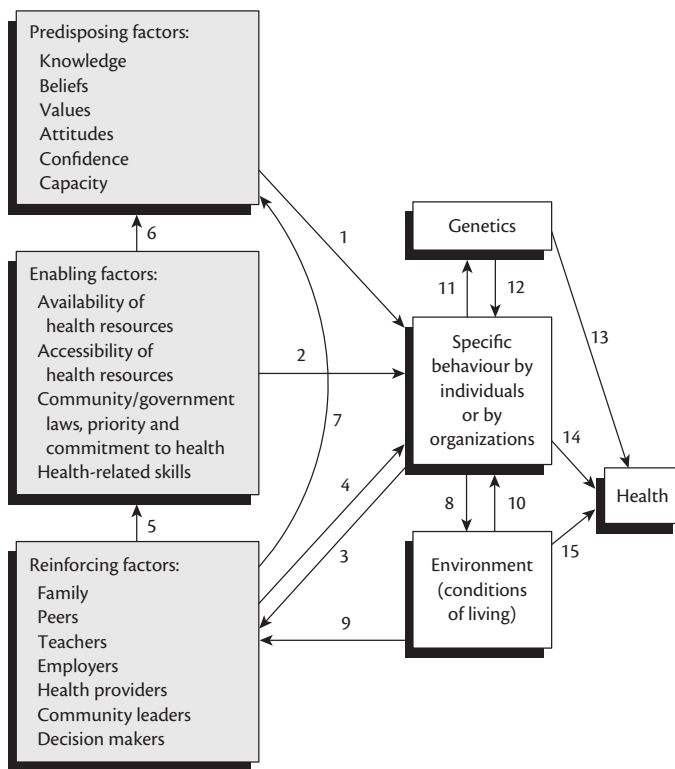

Fig. 2.9.2 This portion of the Precede–Proceed Model includes additional lines and arrows to outline a theory of causal relationships and order of causation and feedback loops for the three sets of factors influencing behaviour. In addition to the lines shown, an arrow from ‘enabling factors’ to ‘environment’ would elaborate the ecological aspect of factors that influence behaviour indirectly through changes in the environment.

individual’s or group’s behaviour. They mostly fall in the psychological domain of determinants, though genetics and environment shape them across the life span. They include the cognitive and affective dimensions of knowing, feeling, believing, valuing, and having self-confidence or a sense of self-efficacy.

Because these determinants of behaviour reside in individuals, public health must seek to influence behaviour by assessing the prevalence and distribution of key predisposing factors and look for opportunities to communicate differentially with various segments of the populations, according to an educational diagnosis or ‘social marketing’ assessment of their knowledge, attitudes, values, beliefs, and perceptions. The behavioural science literature, especially in health psychology, is replete with competing theories of the relative importance of particular predisposing factors and how they interact with each other (e.g. Glanz et al. 2008). Some of these theories, such as the Health Belief Model (Becker 1974), Social Cognitive Theory (Bandura 2004), and the Transtheoretical Model of Stages of Change (Prochaska et al. 2002), have become mainstays of the intervention literature on health education and behaviour change. These frequent uses of selected models have produced sufficient numbers of comparable studies or programme evaluations to permit meta-analyses of their applications across different health behaviours (e.g. Spencer et al. 2005; Tuah et al.

2011). These applications of theory, in turn, have led to enough consistency in the construction of interventions and programmes that these have lent themselves to systematic reviews, notably by national panels such as the Task Force on Community Preventive Services (www.thecommunityguide.gov) and the UK’s National Institute for Health and Care Excellence (<http://www.nice.org.uk>).

Enabling factors

Underplayed in most psychological studies of health behaviour, but critical to the role of public health as a complement to the roles of parents, schools, and mass media in the development of a healthy population, are the enabling factors influencing behaviour. These are often conditions of the environment that facilitate (or impede) the performance of a predisposition or motivated action by individuals or groups. Included are the availability, accessibility, and affordability of healthcare and community resources. Also included are conditions of living that act as facilitators or barriers to action, such as availability of transportation or child care to release a parent from that responsibility long enough to participate in a health programme, clinic, or service. It also includes features of the built environment, such as bicycle lanes, sidewalks, proximity of housing to workplaces, and other physical conditions of the environment that make physical activity more or less convenient and inviting (e.g. Taylor et al. 2007). Enabling factors also include new skills that a person needs—or new capacities that a group, organization, or community needs—to be able to accomplish health goals.

Public health addresses the enabling factors for behavioural change through policy changes and resource allocations at the national, regional, and local level, community organization for such policy and resource allocation at the local level when government programmes and services are insufficient or inappropriate to local perceptions of need. Training in the skills needed to take certain complicated actions is the other behavioural intervention used by public health to address the enabling factors.

In an era of constrained public health resources, many communities have resorted to more intensive community organization to build coalitions of multiple agencies including government and non-governmental organizations, and intersectoral collaboration between the health agencies and the community’s schools, worksites, transportation, and other such sectors. Public–private collaboration on issues of enabling a more healthful food supply in school lunches, for example, or less accessibility of children to vending machines with cigarettes or ‘junk food’, have become increasingly common strategies for addressing the behaviour–environment interaction issues at the heart of most enabling factors (e.g. Institute of Medicine 2012).

Reinforcing factors

Before chronic diseases became the prevailing concern of public health in developed countries, behaviour was perceived as less important than today. The types of behaviour required to implement many of the most important public health interventions such as immunization and fluoridation of water supplies were less complex. Immunizations, for example, could confer long-term immunity for an individual with a single act. Fluoridation or chlorination of water supplies could be implemented in many communities with no engagement of the public,

although when water fluoridation did become a local political issue requiring a local vote, the behaviour in question for most people was, again, a single action. As chronic diseases became more prevalent, the behaviours in question were largely ones that had to be repeated frequently, some for a lifetime, such as dietary practices, hypertension medication regimens, smoking cessation, and physical activity. For these behaviours, the predisposing and enabling factors remain important, but reinforcing factors take on increased importance because maintaining a behaviour requires strong or repeated extrinsic reinforcement in the form of rewards or incentives, or highly internalized intrinsic reinforcements in the form of values and personal commitments.

Reinforcing factors are those consequences of action that determine whether the actor receives positive (or negative) feedback and is supported socially or financially after it occurs. Reinforcing factors thus include social support, peer influences, and advice and feedback by healthcare providers, as well as a sense that the benefits of the action outweigh the costs. In consideration of the benefits (and costs), they also include physical consequences of behaviour, which may be separate from the social context. Examples include the feeling of well-being (or pain) caused by physical exercise and the alleviation of respiratory symptoms (or the experience of side effects) following the use of asthma medication, or gaining weight while quitting cigarettes.

Public health uses reinforcing factors such as denormalizing smoking in public places, social reinforcement with encouraging words in personal counselling, small-group health education sessions in which behaviour is publicly endorsed and praised, or mass media images of attractive role models with whom people wish to be associated by their own behaviour. No matter how effective these extrinsic reinforcements might be in the short term in strengthening a behavioural tendency, they must

be internalized over time to become intrinsic motivation. Token rewards lead to token behaviour if the individuals do not replace them over time with the belief that the behaviour is intrinsically valuable because it accords with their own personal values (Green et al. 1986).

Table 2.9.2 gives examples of the more commonly identified influences on each of four most important behavioural risk factors. These behaviours interact with each other, such that changes in one influence predisposing, enabling, and reinforcing factors for others. Young women, for example, may take up smoking in the belief that it will help them control their appetite and thereby their weight. Other examples are athletes quitting smoking and limiting alcohol intake to improve their physical activity or sport performance; and contraceptive use leading to fewer, more spaced births, which lead in turn to women seeking other opportunities to improve their health and that of their families.

Public health strategies to influence determinants of behaviour

Another chapter will deal with the full range of health promotion and health education strategies (see Chapter 6.4). The focus of this section is specifically on how the aspects of the environment discussed in the previous sections that shape health-related behaviour can be targeted for strategic intervention for public health purposes. Three types of strategies are used in public health to accomplish health promotion and disease prevention goals through behaviour change:

- ♦ *Educational strategies* inform and educate the public about issues of concern, such as the dangers of drug misuse, the benefits of automobile restraints, or the relationship of maternal alcohol consumption to fetal alcohol syndrome.

Table 2.9.2 Some known and suspected predisposing (a), enabling (b), and reinforcing (c) influences on four major behavioural risk factors

Cigarette smoking	Dietary practices	Alcohol use/abuse	Physical inactivity
Knowledge of adverse health effects of smoking (a)	Personal food preferences (a)	Expectations of alcohol effects (a)	Beliefs in physical activity benefits (a)
Attitudes about smoking (a)	Cultural food preferences (a)	Child of alcoholic (a)	Attitudes toward physical activity (a)
Skills in smoking cessation/prevention (b)	Perceived social acceptance of foods (a and c)	Alternatives to alcohol (a and b)	Self-efficacy (a)
Cigarette cost (b and c)	Social context of eating (b and c)	Psychological stress (a, b and c)	Resources, facilities for exercise (b)
Availability of cigarettes (b)	Availability and convenience of healthful foods (b)	Low self-esteem (a)	Cost of exercise facilities (b)
Cigarette advertising (a)	Skills in menu planning (b)	Early drinking experience (c)	Skills in relapse prevention (b)
Peer influences to smoke (c)	Skills in food preparation (b)	Heavy social drinking (c)	Skills in goal setting (b)
Social support for non-smoking (c)	Skills in food selection (b)	Parent and peer influences (c)	Enjoyability of physical activity (c)
Smoke-free policies in worksite (b and c)	Food advertising (a and c)	Alcohol advertising (a, c)	Family support (c)
Access to cessation services (b)	Healthful options in vending machines (b)	Cost of alcohol (b)	Design of the built environment (b and c)
Attitude toward tobacco industry practices (a)	Belief in personal susceptibility to risk factors (a)	Availability of alcohol (b)	Belief in benefits of physical activity

- ♦ *Automatic-protective strategies* are directed at controlling environmental variables, that minimize the need for individual decisions in structuring each behaviour, such as public health measures providing for milk pasteurization, water fluoridation, infant immunizations, and the burning or chemical killing of marijuana crops, but these often involve individual and group decisions and actions about which policies to support, since they limit degrees of freedom in choice of behavioural options.
- ♦ *Coercive strategies* employ legal and other formal sanctions to control individual behaviour, such as required immunizations for school entry, mandatory tuberculosis testing of hospital employees, compulsory use of automobile restraints, and arrests for drug possession or use or for drunk driving.

Illustrative of successful public health measures reflecting this range of strategies directed at influencing health-related behaviours are the efforts to control tobacco consumption. Influencing tobacco-related knowledge and attitudes has been declared one of the great public health achievements of the twentieth century, at least in the United States (Centers for Disease Control 1999) and several other countries. Considering that these successes, as measured by the reductions in tobacco consumption behaviour, were achieved largely in the last third of the century, they represent both a remarkable turn-around of an epidemic of smoking behaviour that had increased inexorably through the first two-thirds of the century, and an inspiration for public health approaches to other health-related behaviours that now show similar epidemic trends. The application of the lessons from tobacco control to reversing, for example, the obesity epidemic through similar influences on dietary and physical activity behaviours has become a point of major public health debate in the early years of the new millennium (Mercer et al. 2005; Green et al. 2006; Eriksen et al. 2007; Institute of Medicine 2012).

Influences on smoking initiation and cessation are numerous, and many of them are also intertwined with diet, alcohol, and physical activity. Predisposing factors include attitudes about smoking and beliefs about and knowledge of the health effects of smoking. Enabling factors of access to tobacco products and price are influential. The price elasticity has been documented at a 3 per cent decrease in tobacco consumption for every 10 per cent increase in the price, and a greater relative decrease in youth, for whom disposable income is less (Ranson et al. 2002; Wilson et al. 2012). The influence of raising taxes on cigarettes, then, has been a major public health strategy with known effects on consumption. With the dedication of part of the tax revenues to the funding of comprehensive tobacco control programmes, some jurisdictions have achieved a doubling and even tripling of the rate of decline in per capita consumption compared with other jurisdictions in the same country (Mercer et al. 2005). But more powerful still are the cumulative reinforcing factors of growing social support and pressure for smoke-free environments as smoking becomes denormalized with the decline in prevalence rates and the legal restrictions on smoking in public places (Eriksen et al. 2007; Wilson et al. 2012).

Cigarette advertising and promotions by the tobacco industry have proved to be powerful negative predisposing and reinforcing influences on smoking behaviour that are highly adaptable to changing regulatory attempts to control their content and channels. Initial restrictions on US tobacco advertising in the broadcast

media in the mid 1960s, for example, resulted in the tobacco industry voluntarily withdrawing from radio and television advertising, but adroitly using those resources from mass media to expand its advertising vastly on more targeted print media in magazines, billboards, and youth-oriented outlets. Sponsorship of sports and arts events and clubs, for example, provided a more targeted venue for reaching youth and other susceptible markets. Response of some jurisdictions in restricting these sponsorships has produced reductions in youth uptake of tobacco products (Hagmann 2002; Perez et al. 2012). Diversification of advertising to youth-oriented media and point-of-purchase settings such as stores near schools has resulted in increased restrictions in many jurisdictions. The restrictions have been largely disappointing, which is attributed to the agility of the industry in finding loopholes and ways to circumvent the new legal restrictions.

Attempts to control the determinants of tobacco consumption also illustrate an essential public health lesson in the importance of comprehensive programmes to affect the complex behaviours associated with chronic diseases (Centers for Disease Control and Prevention 1999, 2007). Comprehensive approaches have proved critical because:

- ♦ No single intervention reaches all segments of susceptible people in a population (Green and Glasgow 2006).
- ♦ No single intervention reaches different segments with the same degree of effectiveness (Warner 2011).
- ♦ Different interventions are differentially effective in the different phases of change (Prochaska et al. 2002).
- ♦ Different interventions variously influence the predisposing, enabling, and reinforcing determinants of behaviour in a population (Green and Kreuter 2005).
- ♦ This comprehensiveness lesson has been carried forward to public health efforts in diet, alcohol, and physical activity insofar as they have increasingly engaged multiple organizations in community coalitions and multiple sectors and national programmes to address the various determinants that extend beyond the purview of the medical and public health sectors at the local level. The complexity of these organizational and ecological layers and intersections of influence on both physical activity and food consumption have driven a concerted effort in the rush to find remedies for the obesity epidemic to include ecological models and systems models (Institute of Medicine 2005, 2010, 2012).

The promotion of physical activity or active living illustrates the lessons of comprehensiveness and multi-sector involvement in public health strategies to influence a complex behaviour. Increasing attention has been given in recent years to the built environment, including the density of housing, mixed-use neighbourhoods, and sidewalks that encourage walking to and from home for shopping, work, and recreation; provision of mass transit that also supports walking the distance to and from transit stops rather than driving to work and other destinations (Frank 2000; Sallis et al. 2012).

The recent growth of the active living field is an extension and integration of traditional public health approaches with more collaborative approaches involving sectors such as housing, parks and recreation, and transportation. It responds to the increasing recognition of the complexity of health-risk behaviours related

to chronic diseases and their numerous determinants. The performance of each behaviour is interwoven with or ecologically embedded in other behaviours, organizations, and ecologies (Ottoson et al. 2009).

Behaviour as determinant of environmental and genetic predispositions

Population behavioural and educational diagnoses enable public health to intervene strategically on the behaviour of populations. But health problems have other determinants in the environment and in genetics. Behaviour also can play a role in influencing those determinants.

The reciprocal influence of individual behaviour on environments

A fundamental precept of human ecology is the reciprocal determinism of behaviour and the environment (Green et al. 1996; Sallis et al. 2012). The literature on health promotion took a sharp turn away from behaviour in the 1980s to give attention to the policy and environmental determinants of health. This was partly in response to a period in which public health was perceived to have taken too much of a psychological approach to the determinants of health (Green 2006). As early as 1968, Edward S. Rogers had appealed to sociology for the assistance public health needed from the social sciences to address the ecological issues (Rogers 1968). Psychologists, however, were more available, at least in the United States, to step into the perceived social science void of public health and to take up the new professorships in public health. They brought an emphasis on testing theories of individual behavioural change. As the ecological imperative of multi-level interventions (individual, family, organizational, community, regional, national, and global) gained growing emphasis in public health (e.g. Kickbusch 1989; Green et al. 1996), a gradual turn to the study of behaviour-in-context gave reciprocal determinism a new lease on life in public health (Stoto et al. 1997; Institute of Medicine 2001, 2003) in the decade bridging the millennium. One theory of behavioural change that gained particular public health prominence in this era was Albert Bandura's social cognitive theory, with its emphasis on self-efficacy and individual agency in changing one's environment at the same time that it gave prominence to the social environment in shaping behaviour (Bandura 2004).

Some of the environmental determinants of health beyond the behavioural control of individuals nevertheless lend themselves to group political behaviour or collective action through community intervention. Communities, neighbourhoods, or special-interest (self-help) groups can organize, vote, lobby, boycott, and otherwise support or prevent some environmental changes. To varying degrees, individuals can avoid or limit their exposure to environmental risks such as solar radiation, lead paint, and ambient smoke. In short, individual behaviour can be mobilized to influence the environment, so that individuals need not be seen only as passive objects of environmental influence.

The projected but still limited mobilization of behaviour to influence genetics

The Human Genome Project and the explosion of research on human genetics have raised very hopeful scenarios of 'personalized medicine', in which individuals could know more precisely

their genetic risk of certain diseases or causes of death. The usual assumptions are that such information could be made readily available to individuals, and that having such information would be considerably more compelling in motivating behaviour than the usual statistical risk of groups of people without the personalized association with the individual in question.

The first assumption remains to be supported by true evidence of effectiveness. For example, in about 30 per cent of women with breast cancer, overexpression of a protein called HER2/neu is associated with a worse prognosis and in such women the drug trastuzumab is especially effective. The US Food and Drug Administration approved the drug and a test for HER2/neu for use in women with metastatic breast cancer in 1998 and more recently for women with early stage breast cancer (Hortobagyi 2005; Braga et al. 2006). The co-development and approval of the drug and test is considered one of the real successes of the application of genetics to modern medical practice and among the best examples of 'personalized medicine'. One might think the story is complete. However, although this information about the efficacy and availability of the test and the drug was published and promulgated by commercial backers, the behaviour of clinicians and their patients has been a more complicated matter. There is little known about how many women have access to testing and treatment. The costs of both are high and cost-effectiveness issues have not been resolved. Also how best to administer the test has not been resolved (e.g. timing) and there are reports of an increased risk of heart failure, the effect of which on acceptance is not known.

The second assumption, that having such information would motivate more concerted effort to change one's behaviour, is only partially supported by: (1) the logic and evidence from other areas of health counselling and communications that more personally tailored health information based on the individual's own family history or biological risk information adds motivational value to the experience with health advice that is based on more generic information (Kreuter and Wray 2003; Kreuter et al. 2005); (2) limited direct evidence from the few instances in which such genetic information has been used to counsel individual behavioural choices of action. The latter is illustrated by the examples in the previous paragraph and those from prenatal testing and counselling for birth defects. However, a meta-analysis of 21 controlled trials showed that while genetic counselling improved knowledge of cancer genetics, it did not increase the level of perceived risk and few studies examined cancer surveillance behaviours (Braithwaite et al. 2006).

Public health faces two major limiting factors in pursuing this pathway of behaviour influencing health through genetic determinants: (1) the limited influence of the genes so far implicated in specific mortality or morbidity outcomes, and their interactions with the environment, and (2) the ethics of offering such information to the individual with anything more than a cautionary note of possible relevance to their reproductive decisions or their behavioural choices. The first is a limit that could be partially overcome with further breakthroughs in the human genomics research. But apart from some prenatal tests for genetic defects in the fetus, most of the other genetic markers associated with predispositions to illnesses or premature mortality are highly interactive with other genes and the environment. Therefore, any course of action recommended to the individual remains probabilistic in its assurance of a health benefit. In combination with the other risk

factors that can be more readily identified, the addition of personalized genetic information might raise the probabilities sufficiently to help the individual reach a tipping point in motivation to take action on complex health-related behaviours. But whether it really adds motivational value to what could be similarly known from a good family history has yet to be demonstrated.

The other limiting factors for this behaviour–genetic pathway as a public health consideration are the ethical complications that arise with the technology and the information. The concern, as in other screening technologies, with false-positive results can be multiplied in their ethical considerations for genetic information on individuals. The usual issues of protecting the privacy of such information and the potential discrimination in hiring, placement, retention, and promotion of individuals with known genetic predispositions will continue to be debated before the ‘personalized medicine’ potential of expanding the behaviour–genetic pathway can be pursued as public health policy. Meanwhile, private medicine is opening opportunities for individuals to explore this option in structuring their behavioural response to personal genetic information, as research on the behavioural implications mounts with three priorities: ‘(1) improving the public’s genetic literacy in order to enhance consumer skills; (2) gauging whether genomic information improves risk communication and adoption of healthier behaviors more than current approaches; and (3) exploring whether genomic discovery in concert with emerging technologies can elucidate new behavioral intervention targets’ (McBride et al. 2010). Other chapters in this volume address human genetics more thoroughly (see Chapters 2.5 and 5.12).

One still speculative pathway for social-behavioural influence on genetics is probed by a review of evidence for developmental and epigenetic pathways linking early life (perinatal) environments with CVD, and critically evaluates their possible role in the origins of African-American racial health disparities in CVD (Kuzawa and Sweet 2009). They observed, ‘extensive evidence for a social origin to prematurity and low birth weight in African Americans, reflecting pathways such as the effects of discrimination on maternal stress physiology’ (p. 2). They concluded ‘environmentally responsive phenotypic plasticity, in combination with the better-studied acute and chronic effects of social-environmental exposures, provides a more parsimonious explanation than genetics for the persistence of CVD disparities between members of socially imposed racial categories’ (p. 2). The prospects for finding ways for behaviour to influence DNA methylation are tantalizing.

The interaction of socioeconomic status, environments, and behaviour

Of all the interactions in the association of behaviour and health, none is more pervasive, consistent, and robust than that of socioeconomic status (SES). The relationship between SES and measures of health or mortality is shown in other chapters to be a gradient rather than a threshold effect, though threshold effects (or points of diminishing returns) are sometimes found beyond which income or other SES indicators have no further beneficial effects (e.g. Finch 2003). Those at the top of the SES hierarchy usually have better health and lower mortality rates than those just below them who are themselves better off than the others below them, and so on down to those in poverty at the very bottom. The

gradient adheres whether the SES measure is education, income, occupational status, or place of residence. The gradient globally is anchored at the lowest end by the poorest developing countries. Some 1.2 billion people globally in 2008 lived in extreme poverty on an income of just US \$1.25 a day, of whom 70 per cent were in Asian and Pacific countries (World Bank 2012). Many of the poor lack access to basic health services and are at exaggerated risks for many of the leading causes of death in those countries. The gradients are complicated by the varied statistical interactions of gender, racial and ethnic discrimination with income, education, and occupation—the usual metrics of SES—in different countries.

The question here is how the mortality and morbidity gradients with socioeconomic status might operate through health-related behaviours, cultures, and environments to suggest mechanisms by which the pervasive SES gradient influences health, and ways in which the behavioural pathway can be made more protective or preventive.

SES as a predisposing determinant of behaviour

The ecological perspective on SES as a determinant of behaviour related to health would suggest first that environments shape behaviour from early childhood onward. Shaping behaviour in the first instance (rather than enabling it in the second or reinforcing it in the third) qualifies this environmental influence as a predisposing factor. Homes, neighbourhoods, towns, cities, regions, and whole countries with their variable physical, social, economic, and cultural environments differ in relation to SES measured at individual, family, neighbourhood, and other geographic levels. Once the measures of SES and health or mortality are aggregated above the individual level, their relationships constitute ecological correlations. Studies have examined the ecological relationship between mortality rates and various indicators of social inequalities in geographical areas varying in size from metropolitan areas (Lynch et al. 1998) to whole countries (Wilkinson and Marmot 1998). These studies showed that those areas where inequalities between those at the top of the hierarchy and those at the bottom were the largest were also those in which the mortality gradient was the strongest (Wilkinson 1996). Similar findings were found with other indicators of social inequities such as differences in social capital (Kawachi et al. 1997). Health disparities between socioeconomic groups appear from Canadian data to increase with age across the lifespan, which supports the notion of a cumulative effect over time of the health- and mortality–SES gradient (e.g. Prus 2007).

One implication of this relative deprivation dimension of the SES–health gradient is that perception of one’s status relative to others de-motivates or discourages one’s efforts to take greater control over the behavioural and environmental determinants of one’s health. Whether consciously discouraged or unconsciously conditioned by repeated confrontations with inequalities and inequities that conspire against one’s efforts, the hypothesis is that disparities make those exposed to relative deprivation less predisposed or motivated to take preventive and healthcare actions. Two specific mechanisms have been suggested for this de-motivation or lack of predisposition to undertake behaviour. One is a chronic pessimism that has been found in adolescent children of lower SES parents, and that pessimism was associated with stress (Finkelstein et al. 2007). The other possibly related mechanism is the theoretical construct of ‘self-efficacy’, widely measured in

association with social cognitive theory applications in health behaviour research (Bandura 2004; Jang and Yoo 2012).

SES as an enabling determinant of behaviour

Socioeconomic standing also confers capabilities and resources that enable the predisposed behaviours to be carried out, for better or for worse. With higher standing come more resources and the associated education and training that endow individuals, families, groups, and communities with enabling judgements, resources, and skills. No matter how motivated people may be by their predisposing factors, they may not have the income and other resources, including accessible and affordable services within reach of their residences or workplaces, to be able to carry out the behaviour without great sacrifice and inconvenience. But environmental variables of accessible fruit and vegetable outlets in local neighbourhoods, for example, only partially explain or mediate the relationship between SES and fruit or vegetable consumption (Ball et al. 2006). The 'food deserts' of poor access to fruits and vegetables in neighbourhood stores of poor areas are compounded by the high accessibility of the 'food swamps' of fast food restaurants with their calorie-dense menus (Fielding and Simon 2011).

The educational enabling influence of SES on behaviour

Among the SES indicators, education has for decades demonstrated the strongest association with most health-behaviour measures (Green 1970a, 1970b; Metcalf et al. 2007), and this association has been found to have a major part of its essence in health literacy (e.g. Curtis et al. 2012). It also stands out among the indicators of inequities in confirming the relative deprivation hypothesis (Kunst and Mackenbach 1994). Education can be viewed as a proxy for a variety of predisposing and enabling factors in explaining the causes of behavioural determinants as mediators of at least part of the SES-health gradient. Prominent among these are optimism (a predisposing factor) and education as an enabling or coping resource (Finkelstein et al. 2007), with the knowledge, attitudes, and skills that come with years of schooling.

The Canadian Health Promotion Survey (Adams 1993) showed that men and women with a higher level of education self-rated their health as excellent or good in a much higher proportion than individuals with lower education (noting that self-rated health is a well-established proxy for objective measures of general health). The proportion of people in Canada who are smokers is double in people with elementary or lower education, compared with people with university degrees (Health and Welfare Canada et al. 1993). This spread in proportions of smokers was greater for the highest and lowest education categories than for the highest and lowest income or occupational status categories (Pederson 1993). Data from the major US community trials in cardiovascular disease prevention showed that the dramatic drop in smoking prevalence over the 1980s was more pronounced for people with higher education compared with people with less education (Winkleby et al. 1992a; Luepker et al. 1993). The same trend was observed in Canada for the period 1985–1991 (Millar and Stephens 1993).

These historical associations between health behaviours and SES have been confounded in the more recent tracking of obesity, physical activity, and food consumption. The more sedentary work

and modes of travel of a majority of white collar workers blur the educational, income, and occupational correlations with physical activity (e.g. Tjepkema 2005; Canadian Institute for Health Information 2006). In Canada, for example, 'of the demographic variables examined, income, occupation, and employment status were unrelated to obesity, while education was negatively associated with the prevalence of obesity' (Raine 2004, p. 6).

The cultural–environmental predisposing influence of SES

The strong relationships between education and smoking and other health behaviours are only slightly less so when adjusted for age, sex, and ethnicity or race (Winkleby et al. 1992b; Shea et al. 1991). Culture and gender do appear to play important roles, but these are highly intertwined with SES and acculturation. The early ecological studies remain some of the most compelling in establishing and explaining the role of culture in health. The studies of Japanese men who had lived in Japan and emigrated to California showed clear dietary changes and increased heart disease and stroke rates only in their offspring, i.e. the second generation. Those who immigrated to Hawaii had intermediate rates of dietary change and coronary and stroke rates (Keys 1970; Kato et al. 1973). As the Japanese became acculturated, they assumed both the dietary and cardiovascular patterns of their new country.

Another classic study providing evidence of the effects of culture on health was the series on the Roseto community. Early observations showed that this ethnically homogeneous Pennsylvania community experienced a significantly lower mortality from myocardial infarction than the nearby community of Bangor despite a higher prevalence of hypertension and obesity and a similar proportion of smokers (Lynn et al. 1967). These results were attributed to the apparent protective effect of a unique social, ethnic, and family cohesion in the community (Bruhn et al. 1982). More recent analyses show that Rosetans lost that relative protection over subsequent decades (Egolf et al. 1992). This loss was accompanied by an increase in the number of intermarriages of Rosetans with people of non-Italian descent, a decrease in social participation in Roseto, and an increase in the general wealth of the community, as the original Italian-born generation was gradually replaced by their ageing American-born offspring (Lasker et al. 1994).

In short, to the extent that minority cultures can remain sheltered from the pervasive influences of the majority culture, they can have powerful predisposing influences on health-related behaviour. With acculturation, however, comes the displacement of minority cultural influence with the majority culture. Culture, nevertheless, remains a conceptually useful construct for understanding both the minority and majority processes of socially transmitted beliefs and values that predispose people to one choice of behaviour over another.

SES as a reinforcing determinant of behaviour

A behaviour that is predisposed and enabled might still fail to persist beyond a trial stage of acting if it fails to produce satisfying results. Satisfaction comes from various sources that can have the effect of reinforcing behaviour. SES can contribute to the availability of reinforcements by putting people into association with other people and environments that are more likely to produce satisfaction with behaviours. Two examples follow.

The 'status identity factor' and social norms

The social-normative theory underlying the notion of SES functioning like a reinforcing factor would predict that people will identify with a place in the social hierarchy that they can justify on the basis of their highest achievement. Unlike the usual measure of SES produced by averaging standardized or weighted measures of education, income, and occupation, one hypothesis derived from social reinforcement theory was that people will aspire to and adhere to that norm of a particular behaviour associated with their highest measure on the gradient of SES. For example, a person who is relatively high on education, but of moderate income and occupational status, would tend to adhere to the behavioural norms of the highest, rather than the average, of the person's three status scores. The hypothesis was tested in a California state-wide sample of mothers of children under 5 years, demonstrating that the immunization status of the children and five other measures of early childhood care followed a gradient with SES, but that the best predictor of the mother's behaviour on these five measures was her highest standardized SES among income, education, and occupation, not the average. This inferred 'status identity' of the mothers provided a basis for linking the psychological phenomena of identification and role modelling with the sociological concept of normative influence (Green 1970a).

Denormalizing behaviour

In retrospect, one of the most important elements of the tobacco control success of the last third of the twentieth century in the United States and Canada was the 'denormalization' of smoking behaviour in public places (Eriksen et al. 2007; Rogers 2010). What had been a normative behaviour of smoking in the workplace and in restaurants, meeting rooms, and other public places became increasingly unacceptable, first by legal restrictions, then by social norms, by which the growing majority of non-smokers expected and even insisted on smoke-free environments. The combination of new smoke-free or 'clean air' ordinances and by-laws with mass media emphasizing the carcinogenic properties of second-hand smoke and the rights of non-smokers to be spared the exposure to this carcinogen resulted in a dramatic drop in this public behaviour. It was during this period of the 30-year decline in smoking that the rate of decline accelerated most dramatically. One reason for the importance of this element of the tobacco control campaigns was that the passage and enforcement of policies restricting a personal behaviour faced strong opposition as long as it was perceived by the public to be a matter of individual rights and the threat to be only to the person's own health. When the threat is seen to be to other people's health, especially to the health of children, the support of passage and enforcement of the laws and regulations grows. Other public health campaigns are attempting to model this experience, which builds on the social responsibility notions associated with communicable diseases of the past, but with most of the chronic disease-related behaviours, such as over-eating and sedentary living, it has been more complicated to relate the normative behaviour of individuals to the health of others.

The interaction of socioeconomic status, gender, and behaviour

Men's and women's relative risk of disease or death in relation to specific behavioural risk factors such as smoking are generally

similar (e.g. Oliveira et al. 2007), but their experiences with health differ markedly (Chapman Walsh et al. 1995). These differences cannot be attributed solely to biological determinants related to sexual differentiation (Krieger et al. 1993). The social construct of gender, as opposed to the biological categories of sex, was conceptualized to refer to cultural and social conventions, roles, and behaviours assigned to men and women (Krieger 1996). These in turn shape the social, political, cultural, and economic circumstances experienced by men and women. Gender thus attempts to capture this differential experience that men and women have with their environment and the possibilities and constraints associated with these differences (Potvin and Frohlich 1998). Some of these constraints and possibilities are interacting with the living conditions associated with SES to shape the health of people (Wilkinson and Pickett 2008).

The correlation of SES with health appears stronger for men than for women; the SES–health gradient is steeper for men (Arber and Cooper 1999), except in their twenties and thirties when the gradients are similar (Matthews et al. 1999). The gender interactions with SES and health have been variously attributed to differential occupational experiences (e.g. Ross and Bird 1994), marital experiences (Koskinen and Martelin 1994), and degree of emancipation of women (Kawachi et al. 1999). These and other possible explanations generally require assumptions of behavioural mediators. Such mediators are as likely to be 'health-related' behaviour (e.g. sedentary living or food consumption patterns) as 'health-directed' behaviour (e.g. exercise or high-fibre diet). This distinction (Green and Kreuter 2005) recognizes the centrality of behaviour in the causal chains even when (perhaps especially when) it is not consciously health-directed behaviour.

Relationships among health-related behaviours

The interplay among habitual behavioural patterns and the socioeconomic and cultural conditions reviewed in the last half of this chapter leads one to put into a broader context the reductionist examinations, presented in the first half, of specific behaviours as they relate to health, disease, and mortality. The dynamic relationships among the specific measures create a complex system of social, economic, cultural, and behavioural factors, interwoven with disease risk factors and health status, and influenced by the healthcare and physical environments.

Early studies of the relationships among health behaviours showed weak correlations, typically below $r = 0.20$ (Green 1970b; Steele and McBroom 1972). Those in subsequent studies that maintained correlations in the 0.20 range were smoking with alcohol use, alcohol use and exercise (Calnan 1989), and smoking and diet (Blaxter 1990). With the decline in smoking, less variation in smoking produces less co-variation with other behavioural variables. Given these low correlations, there is little evidence supporting a one-dimensional concept of health-related behaviours (Calnan 1994) or a uniform 'healthy lifestyle'. It supports, instead, the reciprocal and ecological system of relationships laid out in the various sections of this paper, showing behaviour as both a product and an active ingredient in the mix of culture, socioeconomic and environmental conditions affecting individual and population health.

Conclusion

Behaviour is an inescapable link in the chain of causation between most environmental and genetic determinants and the health outcomes in which they are implicated. Some toxins and infectious environmental agents can affect health directly without behaviour as a mediator, but even these *can* be mediated by individual action to avoid exposures, and collective behaviour of groups or communities to protect themselves.

The *social* environment presents a further complexity in the mediating and moderating of behaviour and environment in their determination of population health. Most health-related behaviour occurs in the context of the social environment, so it involves the behaviour of other people as well as that of the person whose health is in question. The individuals are acting upon, and in reaction to, each other as their health outcomes are being shaped by their actions. This reciprocal determinism of behaviour and the social environment applies as well to the physical environment and the genetic determinants of health. These interactions make up the ecology of health, and call upon public health to take an ecological approach to the management of population health.

One way to structure the ecological approach to the planning of public health programmes in which behaviour change has a role is to examine the factors that influence behaviour in three categories of determinants: predisposing factors, enabling factors, and reinforcing factors. These roughly correspond to strategies, respectively, that would use: (1) direct communications to influence the knowledge, attitudes, beliefs, and perceptions of the population concerning the behaviour–health relationship; (2) legal, engineering, financial, organizational levers, and resource development that would enable, restrain, or prohibit the behaviour; and (3) indirect communications through social organizations, parents, peers, employers, and others who control rewards and approval that would reinforce behaviour. By combining public health strategies directed at these three categories of determinants (predisposing, enabling, and reinforcing factors) the strategies will be comprehensive in their coverage and impact.

All of what has been understood as determinants of the health behaviour of individuals applies with some variation to the behaviour of health professionals, other practitioners and policymakers who could serve as channels through which to reach individuals, groups, and whole populations to influence their health behaviour. The actions of all of these categories of individuals, as well as their organizations, can be analysed in relation to the factors that predispose, enable, and reinforce their actions, and these analyses can point, in turn, to the development of strategies to change those behaviours.

Acknowledgements

We are indebted to Denise Simons-Morton, MD, PhD, and Louise Potvin, PhD, co-authors of this chapter respectively in its first and second editions, for remnants of their earlier contributions that remain in this fourth revision.

Access to healthcare and population health

Martin Gulliford

Introduction to access to healthcare and population health

Facilitating access to healthcare should address the health needs of populations, but the role of health services in improving population health is disputed. Earlier commentators argued that access to healthcare could not be considered as one of the determinants of population health because interventions were generally ineffective at prolonging life and even caused premature mortality through iatrogenic disease (Illich 1976). A more recent consensus is that health services play an important role in delivering clinical interventions for the treatment and cure of disease, as well as population interventions for the prevention of disease and promotion of health. Health services represent one of three key areas of public health activity alongside health protection and health improvement. Public health specialists often play an important role in planning and managing health services. This chapter evaluates the relationship between healthcare and public health; it asks ‘What is the role of health services in improving population health?’.

Concepts and values in healthcare

Purpose and value of health services

The boundaries of health services and health systems are difficult to define (Table 2.10.1). Broader definitions encompass ‘all the activities whose primary purpose is to improve or maintain health’ (Murray and Frenk 2000, p. 718). This definition includes interventions that are not implemented through healthcare services but such multisectoral interventions are generally considered to contribute to health improvement and not healthcare.

Health services serve several objectives. Health services can improve health by preventing or delaying the onset of disability or death; they contribute to relieving pain and suffering; healthcare is also valued for providing information concerning diagnosis and prognosis. Through its influence on individuals’ health status, access to healthcare may determine what opportunities individuals will have in life, and how their lives will begin and end (President’s Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioural Research 1983). Facilitating access to healthcare represents a tangible expression of the value that communities place on life and health.

For individuals, as well as for private providers and commercial interests, healthcare is valued as a private good that can be utilized to preserve or improve health. Markets generally fail to provide a satisfactory distribution of healthcare because the risk of illness is unpredictable, the costs of healthcare can be extremely high, and consumers may have limited information on which to base choices. For these reasons, communities and national governments are usually involved in arrangements for the delivery of healthcare in order to pool risks and regulate healthcare markets. Healthcare also yields benefits that extend beyond individual recipients. The treatment of pulmonary tuberculosis has value in controlling the spread of disease to others. Such positive externalities may be more important to communities than to individuals. Societies may facilitate access to these benefits, as merit goods, which would otherwise be under-produced if individuals only valued their own personal benefits. Extending this argument, it may be desirable to organize healthcare so as to generate public goods that benefit all. Objectives such as the eradication of an infectious disease, or the control of antimicrobial drug resistance, offer benefits that are freely accessible to the global population, with a value that extends beyond national boundaries (Smith et al. 2003).

Guiding principles

Obtaining needed healthcare is sometimes regarded as the responsibility of individuals and families. This is often the case in low-income countries where government or externally funded health services may not be available and families necessarily make out-of-pocket payments to private providers or do not obtain healthcare (van Doorslaer et al. 2006b). In high-income countries, obtaining needed care is sometimes also viewed primarily as an individual responsibility with the government, representing the organized efforts of society, having a minimal role in the regulation of the healthcare market. This libertarian view is often advocated in the United States. One proposed justification is that taxation to provide healthcare for others infringes against individuals’ freedom of choice. From this perspective, fairness only concerns basic opportunities to compete for health resources and does not require that a fair distribution of healthcare is realized. A more moderate position is that individual responsibility may be promoted through the use of co-payments, or user charges, that discourage over-consumption of healthcare and reduce moral hazard. However, such charges generally impact disproportionately on the poor, who generally have

Table 2.10.1 Aspects of health and healthcare

Term	Meaning
Healthcare need	Capacity to benefit from healthcare (Stevens et al. 2004)
Health improvement	Population health benefit associated with intervention on the determinants of health
Health gain	Individual or population health benefit associated with healthcare intervention
Health outcome	Change in individual or population health status associated with utilization of needed healthcare
Health system	(1) All the activities whose primary purpose is to improve or maintain health (Murray and Frenk 2000) (2) The economic, fiscal, and political management method that nations use to run the national healthcare services (Last 2007) (3) A local or regional group of organized health services (Last 2007)
Healthcare	Services provided to individuals or communities by agents of the health services or professions to promote, maintain, monitor, or restore health. Healthcare is not limited to medical care, which implies therapeutic action by or under the supervision of a physician. The term is sometimes extended to include self-care (Last 2001)
Health services	Services that are performed by healthcare professionals, or by others under their direction, for the purpose of promoting, maintaining, or restoring health. In addition to personal healthcare, health services include measures for health protection, health promotion, and disease prevention (Last 2001)

worse health, and can lead to their exclusion from healthcare (Sachs 2012). Many high-income countries have adopted a more egalitarian approach, with the ideal of universal eligibility to services and the objective of equity of access to healthcare (Mossialos and Thomson 2003). This ideal has now been adopted more widely, with a resolution supporting the objective of universal coverage being passed by the United Nations (UN) General Assembly in 2012 (United Nations General Assembly 2012)

The distribution of the outputs of healthcare is also an important concern. From a utilitarian perspective, health services should maximize the health gains obtained across all individuals. This idea is summed up by the slogan ‘the greatest good for the greatest number’. This is sometimes regarded as ‘the guiding principle for many of the decisions and actions of public health professionals’ (Last 2007, p. 385). The objective of maximizing the health gain to be achieved from the available resources is closely related to the economic principle of efficiency. Resources for health will be used most efficiently when health gain is maximized (Table 2.10.2).

The utilitarian approach is problematic because it only requires that the sum of health gains in a population should be maximized, it does not require that all individuals receive a fair distribution of potential benefits from healthcare. In contrast, approaches based on concepts of human rights and social justice view each individual as having a right to health. All individuals are considered to be entitled to healthcare even when the contribution this makes to

the aggregate benefit of the wider community does not require that they receive it (Dworkin 1977). The rights to health and medical care are recognized in the Universal Declaration of Human Rights (United Nations 2007). The International Covenant on Economic, Social and Cultural Rights goes further and requires that governments create ‘conditions which would assure all medical services and medical attention in the event of sickness’ (Office of the High Commissioner for Human 2007). These international statements do not guarantee that access to needed services will be possible for every individual but they are important in offering a degree of protection to marginalized and vulnerable groups (see Chapter 3.5). An approach based on human rights favours a just or equitable distribution of healthcare over the maximization of potential health gains across the population. The pursuit of equity is also justified in terms of Rawls’ theory of justice as fairness, which proposed that a just society will be arranged so as to achieve fair equality of opportunity (Rawls 2007). Daniels (2008) observed that health is an important determinant of the extent of an individual’s opportunities and therefore requires special consideration in a fair society. Based on the concepts of human rights and social justice, equity may be regarded as a moral value which health services should strive to promote (Braveman et al. 2001). Equity and efficiency are often viewed as conflicting objectives. For example, delivering equitable access to specialist services in sparsely populated rural areas may compromise efficiency.

Table 2.10.2 Dimensions for evaluation of health services

Dimension	Description
Effectiveness	Extent to which a healthcare intervention achieves the intended outcome (Last 2007)
Efficiency	Outcome achieved in relation to expenditure of resources (Last 2007)
Equity	Fairness, or justice, in respect of treatment of different individuals or groups (Last 2007)
Access	Extent to which services are available, can be utilized, deliver needed services and achieve appropriate outcomes
Appropriateness	Relevance to need (Maxwell 1984)
Responsiveness	Social acceptability (Maxwell 1984)

However, where health services are both inefficient and inequitable, with costly services delivering suboptimal population health outcomes, widening access to cost-effective services may enhance both equity and efficiency.

The conflicting principles underlying the financing and delivery of healthcare outlined in this section are apparent in the differing approaches to facilitating access to health services in different countries. Existing health systems result from compromises that are made through the policy process. In the healthcare systems of high-income countries, collective healthcare provision based on universal eligibility is favoured but individuals may not be prevented from purchasing healthcare privately. Equity of access is an objective, but this is only to the extent to which it is considered acceptable to compromise efficiency. In other systems, such as in the United States or in middle-income countries, private financing of healthcare through insurance or out-of-pocket payments may predominate, but governments may facilitate access to basic health services for vulnerable groups such as the poor and elderly.

Dimensions for evaluation

The diverse objectives, and the complex organization and delivery of healthcare, require evaluation on several different conceptual dimensions. Maxwell (1984) suggested a framework of six dimensions (Table 2.10.2). Each dimension represents a complex, multi-faceted concept that is not easily defined. Maxwell's dimensions are reflected in the 'National Scorecard' approach used by the US Commonwealth Fund in its 2011 report (The Commonwealth Fund 2011). This used multiple indicators to evaluate five dimensions of health service performance:

- ◆ *Access* including the ability to participate in affordable care.
- ◆ *Efficiency* including appropriate use of resources to deliver cost-effective interventions at appropriate levels of care.
- ◆ *Equity* including the extent of inequalities in health status and eligibility for, and receipt of care.
- ◆ *Quality* including the provision of safe, well-coordinated, patient-centred care.
- ◆ *Healthy lives* including life-expectancy, mortality, activity limitations, and risk factors such as smoking.

Definition of 'access to healthcare'

In general terms, 'access to healthcare' is said to exist when individuals or families can mobilize the resources they need to preserve or improve their health (Gulliford et al. 2002). At the simplest level, having access to healthcare may be judged in terms of the availability of services (Table 2.10.3). This may include the geographical proximity or physical accessibility of services. Availability may also encompass the supply of services in terms of the numbers of doctors, nurses, or hospital beds per 1000 population. At the next level, gaining access to healthcare means that services are utilized when they are needed. There may be considerable barriers to the uptake of services even when these are available. Obstacles to utilization include *affordability* with financial barriers, such as the costs to individuals or households of utilizing care; physical barriers, including distance or difficulties of travel; personal barriers leading to problems of *acceptability*, as when services are not viewed as culturally appropriate, socially acceptable, or consistent with personal beliefs; or organizational barriers, as when there are difficulties obtaining a consultation, or delays in receiving needed treatment, because of waiting lists or limited capacity of services (Aday and Anderson 1981; Pechansky and Thomas 1981). Utilization of services only offers benefit when care provided is relevant to need and effective in addressing people's health problems (Table 2.10.3). Finally, access to healthcare should deliver effective care that meets people's health needs and achieves the intended health outcome.

This traditional, structured approach to the concept of access has been the subject of recent reappraisal. Dixon-Woods et al. (2006) suggested that access should be understood in terms of individuals' *candidacy*, that is their eligibility for healthcare. Candidacy is defined both by individuals' perceptions of their own interests and concerns, as well as by health providers' views of the appropriate roles and spheres of activity for health services. Mooney (2009) argued that access should be understood in terms of the *empowerment* of individuals and communities to gain access to needed health resources. This idea draws attention to the importance of the inequality in power between service providers and more vulnerable service users, in determining who gains access to care, and what services they receive.

Table 2.10.3 Dimensions of access to healthcare

Dimension of access	Meaning	Potential indicators
Availability	Whether there is an adequate supply of health services in an area	<ul style="list-style-type: none"> • Number of physicians or nurses per 1000 population • Number of hospital beds per 1000 population • Distance to nearest primary care provider • Distance to nearest hospital
Utilization	Whether health services are utilized	<ul style="list-style-type: none"> • Primary care consultations for 1000 population • Hospital admissions per 1000 population
Relevance to need	Whether appropriate services are received by people who need them	<ul style="list-style-type: none"> • Proportion of births attended by trained healthcare professional • Proportion of subjects with elevated blood pressure who receive antihypertensive therapy
Outcomes	Whether achievable health outcomes are realized	<ul style="list-style-type: none"> • Maternal mortality rate • Mortality rate from appendicitis

Definition of equity

Equity in healthcare can be evaluated in several different ways (Table 2.10.4). An important distinction, which is attributed to Aristotle, is the one between horizontal as compared to vertical equity (Gillon 2005). Horizontal equity requires that equals should be treated in proportion to their equality, while vertical equity requires that unequals should be treated in proportion to their inequality. It is generally easier to evaluate horizontal equity, as this requires that all people with the same needs have access to the same services, ‘equal access for equal need’. Horizontal inequity in access to healthcare, like inequality in income or health, is often measured using Gini-like metrics known as concentration indices (Mackenbach and Kunst 1997). In reality, different groups in a population often have different needs and require appropriately differentiated services. This is evident, for example, in the healthcare needs of indigenous peoples in Australia whose life expectancy at birth is some 17 years shorter than that of the general population. Mooney posed the question, what would amount to a fair distribution of health resources, given this large difference in health status? (Mooney 1996). There is little consensus on how questions concerning this vertical dimension of equity should be answered. Marginalized groups such as indigenous populations, new migrants, homeless people, or prisoners may be regarded as ‘hard to reach’ or at least ‘underserved’ by standard services and there may sometimes be a case for developing targeted services. There is a concern that such targeted services may become ‘poor services for poor people’. More generally, there is increasing emphasis on designing local services to meet locally expressed needs, leading to greater variation in the organization and delivery of services, in contrast to the uniform approach implied by the pursuit of horizontal equity. In the United Kingdom, the tension between these two dimensions of equity has been addressed by introducing national level service specifications, while accommodating local discretion in organizing their implementation.

In the following sections, approaches to the relationship between access to health services and population health are divided into those that are predominantly motivated by the pursuit of efficiency and those driven by the goal of greater equity. Two specific questions are addressed: ‘How do health services aim to optimize health gains?’ and ‘How do health services ensure an optimal distribution of health gains?’.

Efficiency-oriented approaches

Underlying problems

Lack of effectiveness

Illich claimed that ‘a vast amount of contemporary clinical care is incidental to the curing of disease, but the damage done by medicine to the health of individuals and populations is very significant’ (Illich 1976, p. 23). Illich acknowledged that medicine has some effect in preventing and curing infectious diseases through the use of vaccinations and antimicrobial drugs, but he argued that the historical reductions in mortality from infectious diseases in high-income countries occurred before these technologies became available. In his opinion, treatment of non-communicable diseases such as cancer and cardiovascular disease was of negligible benefit and might cause considerable harm (Illich 1976).

Illich’s interpretation was supported by McKeown’s (1979) analysis of historical trends in mortality in Britain. This analysis was important in identifying the limited role of medicine as a determinant of health in the historical era. For example, relative reductions in mortality between 1881 and 1950 ranged from 30-fold for tuberculosis, 20-fold for digestive diseases, and 15-fold for respiratory disease (Office for National Statistics 1998). Most of these reductions occurred before the widespread use of specific antimicrobial treatment after 1945. These trends support the interpretation that environmental influences, particularly improved nutrition, clean water supplies, and better housing and sanitation, were largely responsible for historical reductions in mortality from infectious diseases in high-income countries with limited gains from health service interventions (McKeown 1979). Wooton (2006) argued that in the historical era, progress in medicine was largely confined to the development of a body of scientific knowledge concerning health and disease. This knowledge was not translated into practical applications and consequently medicine did not develop as a technology for improving health until more recent decades.

A similar argument was developed by Cochrane in his book *Effectiveness and Efficiency* (Cochrane 1972). Cochrane commented on the rising costs of medical care and the dominance of treatment of established disease over preventive medicine. He showed that in many instances there was little evidence available concerning whether medical interventions were beneficial, ineffective, or harmful. When randomized controlled trials (RCTs) were conducted, they often showed that benefits of intervention

Table 2.10.4 Aspects of equity in health and healthcare

Term	Meaning
Equity	Fairness, or justice, in respect of treatment of different individuals or groups (Last 2007)
Horizontal equity	The extent to which equals are treated in proportion to their equality
Vertical equity	The extent to which unequals are treated in proportion to their inequality
Equity in financial contribution	The extent to which individual or household contributions are consistent with their capacity to pay
Equity in access to healthcare	The extent to which there is a fair distribution of access to healthcare in relation to need
Equity in health	The extent to which there is a fair or just distribution of health among individuals and groups in a population
Effective coverage	The proportion of the population in need of an intervention that has received an effective intervention (Shengelia et al. 2005)

were smaller than anticipated and unexpected adverse effects of treatment were not uncommon. Cochrane advocated a now generally accepted view that all healthcare interventions should be tested in RCTs, and the results of all such trials should be systematically collected, analysed, and implemented in clinical practice.

Tradition and professional opinion were, for a long time, the main drivers of clinical practice and the organization and delivery of medical care. However, tradition came under attack through research from epidemiologists and social scientists that questioned the effectiveness of widely used procedures, demonstrated inexplicable variations in clinical practice, widespread problems with medical errors and poor quality of care, and showed that methods for organizing and delivering care were not consistent with patients' wants and needs.

Quality of care and variations in practice

'Quality of care' is a wide-ranging concept that includes departures from optimal standards of healthcare judged on any of Maxwell's dimensions (Maxwell 1984). In Donabedian's framework (Donabedian 2003), quality may be assessed in terms of the organizational structures for care, the processes of care that are delivered, or the health outcomes of care. Problems with quality of care are often revealed through variations in the organization and delivery of care. For example, in Brazil, 72 per cent of women giving birth in private clinics had Caesarean sections, compared with 31 per cent in public hospitals; yet 70–80 per cent of women in either setting expressed a preference for vaginal delivery (Potter et al. 2001). In Pakistan, 68 per cent of subjects in a household survey had received one or more injections for treatment of acute symptoms in the preceding 3 months, with an average of 13.6 injections per person per year. A new needle was reportedly used in only 53 per cent of instances (Janjua et al. 2005). In the United Kingdom, 36 per cent of patients with common colds and upper respiratory infections are prescribed antibiotics (Gulliford et al. 2009). At different family practices the proportion prescribed antibiotics ranged from 0–97 per cent for influenza and 0–84 per cent for common colds (Ashworth et al. 2005).

Variations such as these may originate in uncertainty concerning the optimal use of specific medical interventions. This uncertainty permits the outcome of clinical decisions to be influenced by factors such as the supply of medical services, financial incentives to providers, or practitioner and patient preferences, leading to wide and often idiosyncratic variations in practice. Variations in practice may result in health resources being used inefficiently; in patients being treated in ways that are contrary to their expressed preferences; in the widespread use of potentially harmful procedures; or patients being denied the potential benefits of effective therapy.

Iatrogenic illness and patient safety

Iatrogenic illness and problems with patient safety represent a particular set of concerns with quality of care. Errors in medical care have been shown to be common, especially in hospital settings. In the US Harvard Medical Practice Study of 30,121 subjects from 51 acute hospitals in 1984 (Brennan et al. 1991), injuries caused by medical management occurred in 3.7 per cent of hospital admissions. A quarter of these adverse events were judged to be caused by negligence, 2.6 per cent were permanently disabling, and 13.6 per cent led to death. Based on these results, it was estimated that there may be between 44,000 and 88,000 deaths in the

United States annually from errors in medical care (Kohn et al. 2000). In primary care, there may be significant errors in 0.1–1 per 100 consultations (Bhasale et al. 1998). These include delays in diagnosis, wrong diagnoses, errors in prescribing, failure to prescribe needed treatment, and difficulties with communication and referral (Burgess et al. 2012).

Healthcare-associated infections are an increasing problem. A meta-analysis of 220 reports worldwide suggested that about 15 patients per 100 admitted will experience a healthcare-associated infection, with much higher rates in middle- and low-income countries than in Europe and the United States (Allegranzi et al. 2011).

Misallocation of resources and problems in service organization and delivery

The World Health Organization (WHO) has estimated that between 20 and 40 per cent of all health spending is wasted (WHO 2010). A common problem is over-allocation of resources to hospitals. In high-income countries about 70 per cent of health services expenditure is on hospital services, a pattern of expenditure that has been exported to middle- and low-income countries. Hospital-based services generally deliver interventions of low cost-effectiveness compared with those delivered in primary care (World Bank 1993). Other problems concern the relationship between public and private sectors with doctors employed in the public sector often 'moonlighting' in private clinics, or charging for services provided in public clinics (WHO 2000). The private sector may be inadequately regulated. There is often a lack of respect for the comfort, dignity, and concerns of patients (Phillips 1996; Burgess et al. 2012).

Proposed solutions

Clinical effectiveness and health technology assessment

Cochrane's book *Effectiveness and Efficiency* (Cochrane 1972) was influential in leading to the development of strategies for improving clinical effectiveness, including the promotion of 'evidence-based medicine' grounded in the belief that clinical decision-making should be informed as far as possible by the results of well conducted RCTs that provide evidence for the effectiveness of interventions (Sehon and Stanley 2003). This requires that the results of all available RCTs should be analysed in systematic reviews and meta-analyses such as those produced by the Cochrane collaboration. This approach has been extended to cover not just therapeutic interventions but diagnostic techniques, screening strategies, and methods for delivering care under the more general heading of health technology assessment.

Health technology 'includes any method used to promote health, prevent and treat disease and improve rehabilitation or long-term care' (The NHS Health Technology Assessment Programme 2007). Health technology assessment includes evaluation of both the effectiveness and resource use associated with new medical technologies. Cost-effectiveness analysis is now commonly integrated into the implementation of RCTs so that the cost per unit benefit from an intervention may be estimated. Cost-utility analysis allows the health benefits from different interventions to be compared using a common metric such as the quality-adjusted life year (QALY). This permits more explicit comparison of the benefits obtained, and the resources used by different interventions, thus informing choices made in resource allocation decisions.

Processes for assessing population health needs have also been made more explicit, based on the incidence and prevalence of disease and the effectiveness of interventions, so that health services can be designed to deliver services that are relevant to the population's health problems (Stevens et al. 2004).

Quality improvement, implementation research, and patient safety

The increasing availability of objective evidence concerning effective treatment for different conditions has been associated with increased evaluation of medical care against agreed standards. It is clear that there is widespread failure to achieve standards of good clinical practice or to implement fully interventions that have been shown to be effective in RCTs. For example, the technique of cumulative meta-analysis showed a delay of many years between evidence of efficacy and implementation of thrombolytic therapy in myocardial infarction (Lau et al. 1992). These problems have given rise to a new area of research known as 'implementation research' that aims to evaluate and identify methods to encourage health professionals to practice in accordance with evidence-based guidelines (Eccles et al. 2005). Studies in implementation research typically combine a range of interventions such as the provision of guidelines, invitations to educational meetings, provision of advice from respected peers, or the inclusion of prompts in the medical record. Such combinations of interventions commonly offer modest benefits in terms of promoting evidence-based practice (Oxman et al. 1995). In the United Kingdom, the government introduced a system of financial incentives to encourage family doctors to deliver specified processes of care and designated intermediate outcome targets in their patients, with a main emphasis on chronic illness management (Roland 2004). Initial results appear to be favourable (Doran et al. 2011).

Alongside quality improvement initiatives, and requiring similar techniques for implementation, there have been specific initiatives to increase patient safety. In some countries, special organizations have been set up with the brief of improving patient safety through surveillance of critical events, identifying risks, and feeding back information to improve services. The WHO launched a World Alliance for Patient Safety with a headline campaign of 'Clean Care is Safer Care' focusing on safe blood transfusion, injection and immunization, safer clinical procedures, clean water, sanitation and hand hygiene (World Alliance for Patient Safety 2007).

There has also been increasing recognition of the importance of good governance in health services. This includes both *clinical governance*, to ensure that services deliver safe and effective care that is acceptable to users, as well as *organizational governance*, to ensure that organizational objectives are achieved through effective leadership, accountability, and monitoring, with a specific focus on the use of resources.

Systems redesign and service organization and delivery research

The organizational context in which care is delivered is increasingly viewed as important in influencing the effectiveness and efficiency of care (Sheldon 2001). Whether services are delivered in primary or secondary care, by physicians or nurses, by specialist teams or generalists, the financial arrangements, including the payment and reimbursement methods used, may be important in influencing the costs and outcomes of care. The size and workload

of an organization, its staffing levels, the management strategies, and organizational culture may also influence the quality and safety of services (Mannion et al. 2005). Consequently there has been an expansion of social science-based research into organization and delivery of health services. This includes investigation of the nature of patient and carer interactions with the health system, the roles of the healthcare workforce, or the impact of organizational change on the various dimensions of quality of care (Fulop et al. 2003). At the same time, there has been a much greater interest in experimentation with different models of organizing care including transferring care from hospital to primary and community settings, utilizing staff with different types of training, integrating specialist skills into primary care service delivery, and making use of new information and communication technologies in delivering services. Such changes have sometimes been facilitated by health sector reforms that remove commissioning and service planning functions from the hands of service providers.

Redesign and modernization of service delivery have been particularly important in the management of chronic conditions. Health services have been designed traditionally to deal with acute episodes of illness but most contacts with health services are now for chronic conditions (Bodenheimer et al. 2002). More than two-thirds of adults in high-income countries have one or more chronic conditions, and chronic conditions account for 80 per cent of primary care consultations and 60 per cent of hospital bed days. The management of chronic conditions requires ongoing surveillance of the patient's condition, management of risk factors, early detection of complications, and education of patients so that they can actively manage their own illness and reduce risk through appropriate lifestyle and behavioural changes. Traditionally designed health services are often very ineffective at delivering services that can achieve these outcomes. The US Institute of Medicine referred to a 'quality chasm' representing the discrepancy between the potential for delivering effective care and the reality of chronic illness management (Institute of Medicine and Committee on Quality of Health Care in America 2005). This has led to the development of new models of service delivery in chronic illness care with a focus on developing care in primary settings, linking appropriately trained staff skilled in education and promoting self-care, with easy access to specialist advice, supported by reliable and easy to use clinical information systems (Bodenheimer et al. 2002).

Investing in Health and essential packages of care

The World Bank's World Development Report for 1993 (World Bank 1993) applied the tools of needs assessment, health technology assessment, and cost-effectiveness analysis to model potential solutions to a range of health problems in middle- and low-income countries. The motivation behind the report was summarized in its title, *Investing in Health*. A healthy population is a major resource that can contribute to stronger economic growth and improving standards of living (Bloom et al. 2004). On average each 10 per cent increase in life expectancy at birth in a country is associated with an increase in economic growth of 0.3–0.4 per cent per year (Commission on Macroeconomics and Health 2001). Improved health can lead to greater productivity because there are more economically active adults, fewer dependent adults affected by illness, children who are better able to participate in education

enhancing their productivity as adults, and rising expectations of longevity providing a motivation to save for later life.

The 1993 World Bank Report, and the follow-on second edition of the *Disease Control Priorities* project (Jamison 2007), argued that existing resources for healthcare were utilized extremely inefficiently and that major health gains could be achieved through focused investment in limited packages of highly effective but low-cost clinical interventions and public health measures delivered through health and other services. This investment could be justified in economic terms through the benefits it could bring to productivity and economic growth.

The Global Burden of Disease study and the Disease Control Priorities project were influential in identifying, quantifying, and prioritizing needs for healthcare intervention in countries at different levels of development (Lopez et al. 2006). Using information about the burden of disease and the cost-effectiveness of different interventions it was possible to model the health gain, measured in terms of disability-adjusted life years (DALYs), that could result from different interventions and identify priorities for investment (Table 2.10.5). The World Development Report estimated that a gain of DALYs equivalent to about 25 per cent of the burden of disease in middle- and low-income countries could be achieved through implementation of programmes of low-cost public health interventions, partly delivered through health services, as well as essential cost-effective clinical services (World Bank 1993). A recommended package of essential measures included extended and increased uptake of immunization, improved nutrition education and micronutrient supplementation, treatment of sick children, and reproductive health interventions including prevention and treatment of sexually transmitted diseases and safe motherhood. It was estimated that significant health gains could be achieved with little additional overall cost to governments, through disinvestment from public spending on what it termed 'discretionary clinical services' including interventions of low cost-effectiveness delivered in hospital settings.

The World Development Report contributed to an important shift in thinking in several respects. Providing health services to the poor in middle- and low-income countries was no longer to be regarded as a weak form of buffering against the consequences of poverty. Instead, delivering health interventions to the poor was viewed as attacking the causes of poverty and contributing towards establishing conditions that could lead to economic growth, providing households with a route out of a continuing cycle of poverty

and illness. Following on from the publication of the report, the WHO established a Commission on Macroeconomics and Health (2001) whose report endorsed the importance of preventing and treating disease as a means of promoting wealth as well as health. This facilitated the mobilization of resources for health in middle- and low-income countries. A Global Fund was established to attract funds to be directed towards programmes for the prevention and treatment of AIDS, tuberculosis, and malaria (The Global Fund 2007). The GAVI Alliance (formerly the Global Alliance on Vaccines and Immunisation) was set up to promote immunization programmes in the poorest countries through both public and private sector funding (GAVI Alliance 2007).

The World Development Report was also important in encouraging a more explicit approach to rationing of services and priority setting for health investment, justified by the extent of health gains that could be achieved through this approach. For example, it is estimated that for a cost of US \$1 million the loss of 50,000–500,000 DALYs could be averted through extended vaccine coverage, the loss of 50,000–125,000 DALYs could be averted through improved malaria treatment programmes. Estimates such as these encouraged governments to promote the notion of universal access to essential services. Updated estimates were published for the global burden of disease and risk factors (Lopez et al. 2006) and revised estimates for the costs and effectiveness of different packages of intervention were published (Laxminarayan et al. 2006; Jamison 2007). These included a growing appreciation of the present and likely future impact of chronic non-communicable diseases affecting adults in middle- and low-income countries, together with a recognition that selected interventions for these conditions could be very cost-effective. The WHO has developed the concept of 'effective coverage' (Table 2.10.4) as a measure of the extent to which health services deliver appropriate interventions to those groups of people who need them. Effective coverage is defined as the proportion of the population in need of an intervention that receives an effective intervention (Shengelia et al. 2005).

The thinking in *Investing in Health* was also influential in high-income countries. For these countries, a major implication is that appropriate healthcare as well as population strategies to promote health are important for containing the costs associated with an ageing population and a high prevalence of chronic illness. In the United Kingdom, the Treasury commissioned a former chief executive of a leading bank to examine the case for increasing investment in health services (Wanless 2004). His

Table 2.10.5 Selected cost-effectiveness estimates from the *Disease Control Priorities Project* (2nd ed.)

Service or intervention	Cost per DALY (US \$)	Estimated DALYs averted per million US \$ spent
Care of infants under 28 days old	10–400	2500–100,000
Expanding immunization coverage with standard childhood vaccines	2–20	50,000–500,000
Treating sexually transmitted infections to interrupt HIV transmission	50–200	5000–20,000
Using antiretroviral therapy that achieves high adherence for a high proportion of patients	350–500	2000–3000
Treating myocardial infarction with an inexpensive set of drugs	10–25	40,000–100,000
Performing coronary artery bypass grafting for high-risk cases (e.g. disease of left main coronary artery)	>25,000	<40

report recognized the increasing costs associated with chronic conditions and argued for the need ‘to invest in reducing demand by enhancing the promotion of good health and disease prevention’ (p. 3) with ‘health services evolving from dealing with acute problems through more effective control of chronic conditions to promoting the maintenance of good health’ (Wanless 2004, p. 10).

Criticisms of the essential package of care approach

The essential package of care concept represents a rational, utilitarian approach to addressing urgent health needs in the context of scarcity of resources. However, the projected benefits of the essential package of care approach have rarely been realized through successful implementation (WHO 2013). In reality, the elements of the package must be determined through negotiation, both at the planning stage and during implementation. Pressure from stakeholders, including patients and professionals, may cause the package to be expanded to address other health needs or different elements of care. Proposed disinvestment from specialist services of low-cost effectiveness is unlikely to prove politically acceptable (Gwatkin et al. 2004). Cost-effectiveness analysis is useful in defining the set of interventions that should be delivered by health services but has a more limited role in defining the systems that should be organized to deliver them. A study in Malawi found that although there was an agreed essential package of care, there were important barriers to implementation including insufficient trained healthcare workers and inadequate supplies of essential drugs and equipment (Mueller et al. 2011). The appropriateness of disease-focused intervention strategies has been debated (Taylor et al. 1997; Hopkins 2013). The resources allocated to intensified intervention against a single disease might arguably be invested in long-term efforts to strengthen health systems that can deliver interventions for a range of priority conditions (Taylor et al. 1997). These arguments point to the need for the development of health systems that offer access to affordable care to everyone.

Equity-oriented approaches

Equity in healthcare may be evaluated in terms of the availability and use of health services, as well as in terms of health outcomes (Table 2.10.6).

Availability of services

Table 2.10.6 provides illustrative data for indicators of health services availability for several countries at different levels of economic development (World Bank 2006). It is clear that the countries with the lowest incomes and worst health also have the smallest share of resources committed to health services. In the high-income countries, per capita expenditure on health is some 200 times greater than in the low-income countries and health conditions, measured in terms of life expectancy at birth, are substantially better. These variations among countries illustrate enormous inequality in distribution of healthcare resources, and access to healthcare, at the global level.

Table 2.10.6 also illustrates considerable variation among countries in the same income category. There is variation in the overall level of resources devoted to the health sector; in the relative proportions of public and private sector spending and out-of-pocket expenditure; as well as variation among countries in health outcomes at a given level of expenditure on health. For example, among middle-income countries, Costa Rica has been successful at mobilizing resources for health and life expectancy is higher than expected. Among the high-income countries, the United States is unusual in having exceptionally high health expenditure but life expectancy is lower than expected. These variations reflect societal views of the purpose of health services and the nature of policies, institutions, and community responses to questions of health and healthcare, in addition to the availability of resources.

Health services in middle- and low-income countries do not often provide universal population coverage. Gwatkin characterized health systems in middle- and low-income countries as

Table 2.10.6 Health expenditures, healthcare resources, and life expectancy at different levels of economic development (2010)

	Gross national income per capita (2010 \$)	Health expenditure (per cent GDP)	Public expenditure (% total)	Out of pocket (% total)	Health expenditure per capita (dollars)	Doctors per 1000 population	Hospital beds per 1000 population	Life expectancy at birth (years)
<i>Low income</i>								
Kenya	790	4.8	44.3	42.7	37	–	1.4	56
Pakistan	1050	2.2	38.5	50.5	22	0.8	0.6	65
<i>Middle income</i>								
Albania	3960	6.5	39.0	60.8	241	1.2	2.8	77
Costa Rica	6810	10.9	68.1	27.8	811	–	1.2	79
Indonesia	2500	2.6	49.1	38.3	77	0.3	0.6	69
<i>High income</i>

‘consistently inequitable, providing more and higher quality services to the well-off, who need them less, than to the poor, who are unable to obtain them’ (Gwatkin et al. 2004, p. 1273). In some of the more affluent middle-income countries, such as the small islands of the Caribbean, government services offer access to primary care services that are mainly used by the poor, while private practitioners’ services are utilized by the better off. However, as national income decreases, government expenditure on healthcare as a percentage of gross domestic product (GDP) declines and population coverage by government services diminishes (Table 2.10.6). Services tend to be concentrated close to urban areas, where they may be more readily utilized by better-off groups leading to a markedly pro-rich distribution of expenditure on government health services. The distribution of expenditure on primary healthcare services generally shows a lesser degree of inequity than all healthcare spending (Fig. 2.10.1). In rural areas, access to government health services may be extremely limited, with non-governmental organizations such as religious bodies and charities sometimes offering alternative sources of provision. Geographical barriers to accessing services are important not only in terms of distance but also in terms of the difficulty and costs of travelling long distances to access services. In some regions, the rapid pace of urbanization may lead to situations in which large populations of urban poor may have limited access to any health services.

In China, the lack of availability of rural health services was addressed between 1965 and the early 1980s by the development of ‘barefoot doctors’. These were rural farm workers who were given basic health training over several months in order to provide a combination of traditional Chinese and Western medicines to rural communities. The ‘barefoot doctor’ approach was regarded

as a model for the development of community health workers in other countries and provided an important inspiration for the 1978 Alma Ata Declaration that initiated the ‘Health for All’ strategy. The Alma Ata Declaration promoted access to primary care, with an emphasis on community participation and universality, as a means of facilitating equity in health. The importance of the concept of primary healthcare was restated in the 2008 World Health Report (WHO 2008) which advocated primary care as a route to reducing inequalities in health outcomes.

Definition of primary healthcare

There are several definitions of primary healthcare. The WHO makes a distinction between primary healthcare, which encompasses public health activities directed at environmental determinants of health, and primary medical care, including first point of contact care in the community. The English Department of Health defines primary healthcare simply as care provided outside hospitals by family health services (including family physicians, dentists, pharmacists, and opticians) and community health services (including community doctors, dentists, nurses, midwives and health visitors, and other allied professions). Other definitions characterize primary healthcare according to key attributes (Table 2.10.7). Primary care providers are community based, easily accessible, and offer population coverage. Primary care provides the first point of contact with the health system and is comprehensive in its scope, addressing all potential health problems. Primary care also provides ongoing care over time

Table 2.10.7 Primary medical care: definition and key elements

Definition of primary medical care	
Care which provides integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal healthcare needs, developing a sustained partnership with patients, and practising in the context of family and community (Institute of Medicine 1994)	
Characteristics of primary medical care	
Attribute	Meaning
Universal	Population-based, open to everyone
Accessible	Enabling people to use services when they are needed
Community-based	Placing the patient within the wider familial or social context necessary for addressing multiple causes of illness
First point of contact	Providing entry into the health system
Comprehensive	Addressing most personal care needs including preventive, curative and rehabilitative
Continuity	Providing care that is patient-focused over time
Coordination	Coordinating and regulating use of other levels of care
Affordable	Consistent with capacity to pay

with continuity or longitudinality representing a key element in most definitions. Primary care services are generally less costly and more affordable than specialist services. In high-income countries, primary medical care practitioners generally have a gatekeeper role in which they regulate and coordinate access to specialist care (Starfield 1992). However, specialist expertise is increasingly being embedded in primary care teams in order to improve the quality of chronic illness management (Bodenheimer et al. 2002).

Through its emphasis on universality, accessibility, and affordability, primary medical care generally promotes equity of access to healthcare. Through its community orientation and emphasis on out-of-hospital care, primary medical care generally enhances efficiency through the application of more cost-effective and appropriate health technologies. The gatekeeper role of the primary care practitioner generally has the consequence of promoting more efficient utilization of resources compared with systems where individual patients can gain direct access to specialists.

Inverse care law

Inequality in the availability of health services is a concern for all countries. Without regulation, the supply of healthcare resources is distributed towards more affluent areas with fewer health needs. This situation was described by the British general practitioner Julian Tudor Hart as an ‘inverse care law’ with ‘the availability of good medical care tending to vary inversely with the need for it in the population served’ (Tudor Hart 1971, p. 405).

In countries which, like the United Kingdom, have a dominant national health service funded from general taxation, this situation has been addressed through the development and application of explicit formulae linking the allocation of resources for hospital and community services in different areas to measures of population size and health needs. The number of primary care doctors in an area is also regulated. Nevertheless, historical patterns of the supply of services have been resistant to change and socioeconomically deprived areas continue to have fewer doctors and less well-developed primary care facilities. Similar resource allocation methods have been recommended for application to public services in middle- and low-income countries (Laxminarayan et al. 2006.) In countries, with more pluralistic systems of providing care, or where fee-for-service payment is dominant, greater inequities in the supply of services develop. For example, in US cities the poor are significantly ‘underserved’ by health services both because of inequalities of supply and because of financial barriers to accessing care (National Research Council 2003). In most countries, the rural poor are significantly disadvantaged by relative or absolute lack of availability of services.

Availability of primary care and population health

Does the availability of primary healthcare contribute to improved population health? In general, those countries that have followed policies emphasizing universal primary healthcare coverage have achieved more favourable health outcomes. The Cuban health system is frequently cited as one that has successfully adopted the primary care approach. In 2009, life expectancy at birth in Cuba was 76 years in men and 80 years in women, compared with 77.4 years in the United States, and the infant mortality rate was 7.2 per 1000 in both countries in spite of the great disparity in economic conditions (Pan American Health Organization 2007). In Costa Rica, commitment to the development of public health

services and primary care has been associated with favourable health outcomes and the second highest life expectancy in the Americas (Table 2.10.6) (Unger et al. 2007).

Evidence is also provided by ecological analyses from high-income countries. In the United States, states with a greater supply of family physicians have lower mortality rates after adjusting for income inequality and smoking (Shi et al. 1999). In the United Kingdom, districts with higher supply of family physicians have lower mortality from all causes but this association is sensitive to adjustment for several measures of healthcare needs. Hospital utilization shows a strong negative association with the supply of primary care physicians (Gulliford 2002). In an analysis of data for 18 Organisation for Economic Cooperation and Development (OECD) countries, Macinko and colleagues (Macinko et al. 2003) suggested that the strength of a country’s primary healthcare system is associated with lower all-cause mortality and reduced premature years of life lost from all causes and from respiratory and cardiac disease.

Utilization of services

Donabedian (2003) argued that utilization of services represented proof of access to healthcare. The availability of services does not ensure that those who need them will use them and there may be important personal, financial, or organizational barriers to the uptake of services. Patterns of utilization may not be consistent with medically defined need, as when people do not take up preventive services, delay in presenting with serious conditions, or utilize services for apparently trivial conditions. In many health systems, the financial cost of utilizing healthcare may present a very significant barrier to utilization. McIntyre and colleagues (McIntyre et al. 2009) identified *affordability* and *acceptability* as important dimensions of access, alongside service *availability*.

Financial barriers to access

Fees paid by service users as out-of-pocket expenditures are important in funding healthcare in middle- and low-income countries (Table 2.10.6). This impacts disproportionately on those who are poor or sick (WHO 2010). This has the consequence that poor people may be unable to obtain needed healthcare, or may find it necessary to utilize less costly and less appropriate forms of care such as private drugs vendors. People may delay accessing care until their illness becomes more severe, requiring more costly treatment. Health expenditures for serious illness may then be catastrophic leading to impoverishment of households. Xu and colleagues (Xu et al. 2003) reported a study of catastrophic health expenditures, defined as health expenditure exceeding 40 per cent of household income after subsistence needs were met. More than 2 per cent of households in 17 out of 59 countries experienced catastrophic expenditures. Based on between-country comparisons, high healthcare expenditures were more likely if health services require direct out-of-pocket payment, if households have limited capacity to pay, and if methods to pool risks were lacking. In Asia, illness is one of the principal reasons for households falling into poverty. Across eleven Asian countries, if household expenditures on healthcare are taken into account, then an additional 2.7 per cent of the population (78 million people) live in absolute poverty with household incomes of less than US \$1 per person per day when compared with conventional estimates (van Doorslaer et al. 2006b). Frenk observed a paradox that while healthcare should be

an important factor in reducing poverty, expenditure on health-care is itself a cause of poverty (Frenk 2006).

The 2010 World Health Report (WHO 2010) analysed these issues and advanced the principle that there should be reduced reliance on direct, out-of-pocket, payments for healthcare, with greater use of 'pre-payment' through taxation or insurance to finance health-care. These approaches should provide a mechanism for increasing population coverage, with the risk of illness pooled across the population, so that healthcare for the sick is under-written by the healthy, and for the poor by the wealthy (WHO 2010, p. 5). This approach was subsequently endorsed by a UN resolution in 2012. Recent Mexican health reforms provide an example from a middle-income country, with the introduction of a new form of health insurance that extended coverage of the poor and provided access to a set of basic medical interventions (Frenk et al. 2006).

Sachs (2012) suggested that, in low-income settings, 'universal coverage' should be understood in terms of coverage with a minimum package of low-cost interventions to meet basic health needs. This should initially focus on maternal and child health needs, communicable disease control, and nutrition, with a more selective approach for non-communicable diseases and injuries. However, universal access to even a minimum package might cost considerably more than the maximum available revenues in a typical low-income country indicating a requirement for substantial additional external resources to achieve universal coverage (Sachs 2012).

Healthcare utilization in high-income countries

Many studies have evaluated the overall impact of barriers to the utilization of medical care in high-income countries that, with the exception of the United States, generally offer universal healthcare coverage. In a recent study, the utilization of physician services was evaluated in relation to respondents' self-rated needs for care (van Doorslaer et al. 2006a). Gini-like indices of horizontal inequity were estimated to summarize the utilization of care in relation to household income level. The results showed that utilization of primary care visits was generally either equitably distributed among income groups, or showed a pro-poor distribution. However, utilization of specialists' services generally showed some degree of pro-rich inequity, that is higher-income groups utilized more specialist care than lower-income groups at a given level of need. This is a consistent finding from a number of studies and suggests that higher socioeconomic position, including higher income or education, may facilitate access to specialist care through increased ability to negotiate financial or organizational barriers. These results from a range of countries suggest that in many instances a degree of equity of access to primary care has been achieved, but inequity persists in the utilization of specialist care.

Socioeconomic groups differ not only with respect to the volume of care consumed but also with respect to the type of care utilized. There is a considerable body of evidence to show that preventive medical interventions are taken up less by lower socioeconomic groups, with a risk of increasing inequalities in health. In Belgium, for example, overall utilization of family physician services showed substantial pro-poor inequity, but there was marked pro-rich inequity in the uptake of influenza vaccination, cholesterol testing, mammography, and cervical cancer screening (Lorant et al. 2002). Problems of poor quality care typically vary between socioeconomic groups with disadvantaged groups receiving lower quality care. The US Institute of Medicine has

reviewed a large and consistent body of evidence to show that US black and ethnic minority populations are less likely to receive needed care even after allowing for socioeconomic variables including insurance status, income, age, and severity of condition (National Research Council 2003). For example, there are lower rates of utilization of appropriate cardiac treatment including coronary artery bypass surgery, lower rates of renal dialysis, or transplantation, but higher rates of unfavourable events such as diabetes-related lower limb amputations.

Healthcare and population health

Perceptions of the role of health services as a determinant of population health have evolved. Historically, medical care was of limited importance as a determinant of health; medical care was often ineffective and had a considerable capacity for causing harm. In the twentieth century, however, the pace of technological innovation accelerated and from 1948 onwards the application of RCTs to evaluate the effectiveness of health technologies was increasingly accepted. Effective interventions came to be widely used. These included vaccination and immunization against infectious disease, screening for early stages of cancer, treatment of risk factors for cardiovascular disease, or treatment services for the major causes of mortality. The impact of the widespread implementation of such interventions on population health is difficult to evaluate because of the contribution of wider and more powerful determinants of population health cannot be readily controlled as they might be in a randomized trial. Three main approaches have been used to evaluate the impact of healthcare on population health indicators.

The 'sentinel indicator' approach supposes that if a given condition is amenable to medical intervention, then there should be few or no deaths from the condition. Mortality rates may be used as sentinel indicators of the effectiveness of healthcare services. For example, if surgical services are effective then there should be few deaths from acute appendicitis, cholecystitis, or abdominal hernia. This method was developed and implemented extensively by Holland (1991) who mapped the distribution of 'avoidable' deaths in Europe.

If a health service intervention is implemented across a population over a short space of time, changes in trends in mortality or morbidity may be used to evaluate the effectiveness of the intervention. There have been well-documented reductions in the incidence of infectious diseases following the implementation of new vaccination programmes. There have also been changes in mortality from cancer following the implementation of screening programmes. This approach is complicated by underlying secular trends in disease incidence as well as by changes over time in the effectiveness of case management.

Modelling approaches to the evaluation of health service effectiveness vary in their sophistication but all utilize evidence concerning the incidence and prevalence of disease, the effectiveness of clinical interventions, and the expected coverage and quality of services in the population at risk. This information is used to estimate the contribution of medical care to real or projected changes in mortality or other health outcomes in populations of interest.

Healthcare and population health: high-income countries

Bunker and colleagues (Bunker et al. 1994) modelled the contribution of medical care to life expectancy in the US population.

Their report concluded that medical care, including preventive and treatment services, contributed about 5 years additional life expectancy in the United States with potential for gain of an additional 1.5–2 years if effective interventions were implemented more completely, with improved population coverage, and higher standards of care. In a more recent study, Cutler et al. (2006) estimated changes in life expectancy at birth in the United States between 1960 and 2000. The cumulative increase in life expectancy during this period was 6.97 years with reduced mortality from cardiovascular disease accounting for 4.88 years (70 per cent) and reduced rates of infant deaths accounting for 1.35 years (19 per cent). Based on Bunker's estimates, as well as analyses of the decline in mortality from cardiovascular disease (Unal et al. 2004), Cutler et al. (2006) attributed half of this increased life expectancy to more effective medical intervention. Several examples illustrate the substantial benefits to be obtained from effective medical care.

Survival with human immunodeficiency virus

The first illustration concerns the survival of people who are infected with the human immunodeficiency virus (HIV). Lohse et al. (2007) compared the survival of HIV-infected individuals in Denmark with that of controls matched for age, sex, and place of residence drawn from the general population. The estimated median survival of incident HIV cases after 25 years of age was 7.6 years in 1995–1996, 22.5 years in 1997–1999, and 32.5 years in the period 2000–2005. This dramatic improvement in survival following diagnosis was attributed to the introduction of highly active antiretroviral therapy (HAART). This improvement is all the more remarkable when it is remembered that HIV was first identified in 1984. This example illustrates the capability of medical care to change the clinical course of a condition. In this case HIV became a chronic disease requiring active medical therapy over many years, with a prognosis similar to that of insulin-treated type 1 diabetes mellitus. Indeed, before insulin treatment became available, the prognosis of type 1 diabetes was similar to, or worse than, that of HIV infection in the pre-HAART era.

Breast cancer mortality

Another example concerns mortality from breast cancer, the most frequent cancer among women in high-income countries. In the United Kingdom, population-based mammographic screening was introduced for women aged 50–64 years after 1988. The decision to introduce screening was based on strong, but disputed, evidence from RCTs (Gotzsche and Olsen 2000; Nystrom et al. 2002). Around this time, there was also accumulating evidence for increasing survival following clinical diagnosis through more effective use of specific therapies, including the oestrogen receptor antagonist tamoxifen as well as other newer drugs. An analysis of breast cancer mortality for women aged 55–69 years in England and Wales, showed an estimated 21.3 per cent reduction in breast cancer mortality between 1990 and 1998 compared with the predicted trend (Blanks et al. 2000). The authors estimated that approximately one-third of this decrease could be attributed to breast cancer screening with two-thirds of the reduction attributed to improved treatment. Allgood et al. (2008) compared women who died of breast cancer with control women who did not die and found that attending for breast screening was associated with between a 35 per cent and 65 per cent reduction in odds of mortality depending on assumptions. Cancer Research UK

(2007) reported that 5-year survival of women diagnosed with breast cancer increased from 52 per cent in 1971–1973 to 85 per cent in 2005–2009. The example of breast cancer illustrates the difficulty of analysing longer-term outcomes of health service interventions. Analysis required estimation of the secular trend, in this case increasing, as well as separate effects of a population screening intervention and the outcomes of improved clinical treatment.

Coronary heart disease mortality

These same difficulties are also evident in the third example, which concerns the impact of healthcare on declining mortality from coronary heart disease (CHD). In Finland, as in a number of other high-income countries, CHD mortality has been declining since the 1960s. During the 1980s and 1990s a number of new therapies were introduced, whose effectiveness had been demonstrated in large RCTs. These included more effective drug therapy for patients with myocardial infarction, angina, or heart failure as well as coronary artery bypass surgery for patients with angina. There were also declining trends in the major risk factors for CHD including elevated cholesterol and blood pressure levels and cigarette smoking. Based on observed trends in risk factors and uptake of specific therapies, Laatikainen and colleagues (Laatikainen et al. 2005) estimated that about 53 per cent of the reduction in CHD mortality in Finland between 1982 and 1997 could be attributed to changes in risk factor levels, while 23 per cent could be attributed to more effective medical care, including secondary prevention, in those affected by the condition. In England and Wales, CHD mortality declined by 62 per cent in men and 45 per cent in women between 1981 and 2000, and about 42 per cent of the decline was attributed to medical intervention (Unal et al. 2004).

These analyses of CHD trends and their determinants raise important questions concerning the priority to be given to prevention efforts through population strategies as compared to healthcare intervention, contributing 'high-risk' approaches to primary prevention and to secondary and tertiary prevention in those with established disease. Comparison of the potential costs and outcomes of population strategies for primary prevention, as compared to medical care intervention, should generally favour the former. However, the dominant epidemiological approach to evaluation, the RCT, lends itself most readily to the evaluation of medical care interventions. The application of epidemiological designs to the evaluation of population-wide prevention strategies has generally given disappointing results (Ebrahim and Smith 2001). This may have encouraged epidemiologists to give undue priority to medical care interventions with less attention given to the implementation and evaluation of population strategies. For example, Wald and Law (2003) used the results of meta-analyses of clinical trials to support the concept that a 'polypill' containing a number of effective but low-cost pharmaceuticals (a statin, three blood pressure-lowering drugs, as well as aspirin and folic acid) may have the potential to prevent up to 80 per cent of stroke and CHD deaths. However, a pill is not a panacea for a lifetime of exposure to unhealthy risks and a strategy grounded in the high-risk approach may not be appropriate for population-wide implementation.

Access to care and inequalities in health

In high-income countries, the consequences of inequities in healthcare access may not be easy to discern because problems resulting from inadequate healthcare are not easily distinguished

from the consequences of inequalities in the wider determinants of health, often sustained over generations. Here, promoting a greater degree of equity of access to healthcare than already exists is not usually viewed as a major strategy for reducing inequalities in health. Instead, inequalities in the wider determinants must be addressed more directly. This does not mean, however, that it is not important to ensure that all groups have equal access to the benefits offered by effective healthcare interventions, with access to preventive medical interventions over the life-course being key to reducing inequalities in healthy life expectancy (Acheson 1998).

Some indirect evidence suggests that inequity in access to specialist care may contribute to inequalities in health in high-income countries. In England and Wales, there are substantial socioeconomic inequalities in survival with cancer that have been increasing over time and are greater for treatable cancers (Coleman et al. 2004). For example, the difference in 5-year survival between the highest and lowest quintiles of deprivation in women is 5.8 per cent for breast cancer, 8.3 per cent for rectal cancer, and 7.3 per cent for colon cancer, compared with 0.2 per cent for oesophageal cancer, a less treatable condition. Evidence such as this has been used to advocate the routine implementation of 'equity audit' as part of routine service evaluation. In the United States, there are significant black-white inequalities in mortality, with life expectancy for black men being 6.3 years lower, and for women 4.5 years less, than for white people. Cardiovascular disease and diabetes account for 35 per cent of this difference in men and 52 per cent in women (Harper et al. 2007). Differential access to healthcare may contribute to these differences (National Research Council 2003).

In order to promote equity in health, new policies and services have sometimes been implemented on the basis of their potential to reduce inequalities in health. In England, following a White Paper on cigarette smoking, smoking cessation services were developed in deprived areas, providing nicotine replacement therapy free of charge (Chambers 1999). Universal antenatal and newborn screening programmes for sickle cell disease and thalassaemia were implemented with specific recognition of their potential to reduce health inequalities associated with black and ethnic minority status (Sassi et al. 2001). At local level, outreach services have been developed to target specific groups such as homeless people with serious mental illness.

Healthcare and population health: middle- and low-income countries

Millennium Development Goals

While sentinel events, such as maternal and child deaths, are an infrequent occurrence in high-income countries, this is not so in middle- and low-income countries. The health-related Millennium Development Goals (MDGs) were designed to reduce maternal and child mortality, as well as reducing deaths from tuberculosis, malaria, and other diseases. Focused strategies for intervention have been advocated to achieve these objectives. There are four main strands to the strategy to reduce child mortality, including better treatment of complications for newborn infants, integrated management for childhood illnesses, expanded programmes for immunization, and improved nutrition for infants and young children. In the context of a 2015 target for the achievement of the MDGs, reports have evaluated progress towards these targets. Rates of maternal and child deaths have been declining overall, but

the rate of decline is generally lower in those regions with highest mortality rates (Lozano et al. 2011). At present rates of progress, it is unlikely that the targets for health outcomes will be achieved until considerably later than intended, reflecting continuing difficulties in accessing healthcare. At the same time, the growing prevalence of chronic non-communicable diseases coming on top of an existing high burden of infectious diseases, is contributing to a 'double burden' of disease in middle- and low-income countries. The importance of universal health coverage has therefore received increasing attention as a key route to addressing these problems (WHO 2010) and was advocated by a resolution of the UN General Assembly in 2012 (United Nations General Assembly 2012). There are many obstacles to achieving universal coverage, including the absolute shortage of resources in the poorest countries, weak governance in public services, and problems in the relationship with the private sector (Moreno-Serra and Smith 2012; Sachs 2012). However, recent empirical analyses suggest that there are substantial population health benefits associated with increasing access to health services by increasing government health expenditures and reducing the share of out-of-pocket health expenditure (Moreno-Serra and Smith 2012).

Conclusion

This chapter started by asking 'What is the role of health services in improving population health?'. It went on to distinguish two separate questions: 'How can health gains be maximized?' and 'How should health gains be distributed?'. The negative argument that health services have little impact on population health is untenable. Modern healthcare offers a wide range of interventions of proven effectiveness that when implemented widely can be shown, at least indirectly, to contribute to improving trends in population health status in countries at different levels of economic development. Population health gains can be increased by investing resources in the most cost-effective interventions, by increasing effective coverage of the population, increasing quality of care, and optimizing systems for organizing and delivering care. Inequalities in health continue to be sustained by the inequalities in distribution of the determinants of health both within and between countries. While a degree of equity of access to primary care has been achieved in high-income countries, this is generally far from being the case in middle- and low-income countries. The challenge now is to ensure that all groups obtain a fair share of the benefits of healthcare intervention. Public health specialists should advocate principles of efficiency and universal coverage and contribute to realizing these through participation in processes of needs assessment, health technology assessment, quality improvement, and facilitating access to needed healthcare for all groups.

3.1

Leadership in public health

Manuel M. Dayrit and Maia Ambegaokar

Introduction to leadership in public health

Imagine that tomorrow you were suddenly appointed into a prominent health leader position in your country—as a Director of Department or perhaps even Minister of Health. Upon taking office, you are presented with the following urgent dilemmas by your chief advisers:

- ◆ We are suffering perennial outbreaks of water-borne diarrhoea in the urban slums of our largest city, caused by the illegal tapping of water lines. How can we prevent this in both the short and long terms?
- ◆ Other departments are preventing us enacting any measures to stop smoking in public places. How can we convince them to collaborate on this critical health issue?
- ◆ How can we take steps to provide antiretrovirals for the tens of thousands of our citizens suffering from HIV/AIDS?
- ◆ Our government is in moral opposition to abortion, despite scientific evidence showing that decriminalizing abortion prevents maternal deaths from sepsis. Illegal abortion is high in our country. What action should we take?

How would you proceed to address these issues? Would you be able to think on your feet and respond promptly and effectively to the health needs of your populace? In other words, are you capable of being a public health leader?

Think about these questions as we explore the nature of leadership and the possibility of learning it.

Overview of leadership in public health

There is growing recognition of the importance of leadership in public health. This is reflected in recent domestic and international initiatives to train or ‘develop’ leaders in the health sector (Wright et al. 2001; Cardenas et al. 2002; Saleh et al. 2004; Umble et al. 2005), to identify the skills and personal qualities of leaders (Wright et al. 2000; NHS Leadership Centre 2006), and to assess the effect of different types of leadership on outcomes (Firth-Cozens and Mowbray 2001; Xirasagar et al. 2005). In this chapter, we examine what is involved in public health leadership. We set four tasks: to define the difference between management and leadership; to describe the core competencies and personal

characteristics of leaders; to discuss whether leadership can be taught; and to demonstrate why leadership is so important in public health. We argue that it is the complex, multiorganizational, and team-based nature of health work that necessitates leadership at many levels in order to result in success.

There is an urgent need around the world for strong public health leaders to promote the health of populations, particularly the poor and vulnerable. Unfortunately, calls for stronger and better leadership are often taken as imprecise and unachievable demands. In this chapter, we attempt to circumvent that accusation by demonstrating that effective leaders have existed and continue to exist in health, and that strong leadership can be encouraged and developed. In addition, we have built the chapter on findings from interviews with individual health sector leaders.

At the end of the chapter, we turn to the targeted reader of this book—an early-to-mid-career public health worker—and suggest ways to develop his or her own ‘path to leadership’. We urge the aspiring health leader not to forget the inseparable link between what is needed for leadership to occur and the kind of principled leadership most required in global health today.

Among the chapter’s most important points:

- ◆ There is a distinction between leadership and management. Leadership has to do with the visionary activities of setting direction, while management has to do with the controlling tasks associated with implementation.
- ◆ Leadership is fundamentally about influence. Academic thinking about leadership has evolved from a focus on the characteristics of the individual leader to a more complex understanding of the dynamic interaction between leaders and followers in specific contexts. But there is no established ‘science of leadership’, as there is in medicine.
- ◆ Public health leaders need to be able to imagine and create evidence-based change. They need to be able to influence and lobby key actors for support of their public health agenda. They must operate across disciplinary and organizational boundaries, and they must be skilled at developing and working through diverse teams.
- ◆ Leaders are not simply born. Public health leaders can be developed by means of team-based training, mentoring, and repeated practice of leadership skills at all levels and all types of public

health organizations. The aspiring health leader can create her or his path to leadership.

- ♦ Public health challenges are often politically and procedurally complex and do not lend themselves to simple medical or technical solutions. A set of guiding principles will help the leader to define appropriate actions.

Leadership is not the same as management

Much literature and research conflate leadership and management, but the two are not identical:

‘Management’ derives from the Latin word ‘manus’ (meaning hand) and the subsequent Italian word ‘maneggiare’ (to control, often horses)... ‘Leadership’, however, is from the Old German word ‘Lidan’ and the Old English derivation ‘lithan’ (to travel, to show the way, to guide). (Grint 2002, p. 248)

This distinction between the controlling tasks associated with implementation and the visionary activities associated with setting a direction is a useful, if simplified, way of defining management as compared to leadership. In practice, the two are often linked, in a single individual or in a particular job description. As a result, separating the characteristics of good leadership from those of good management is not straightforward.

To a certain extent, the confusion arises because historical reviews of research on leadership often begin with the early research on what makes a good manager. For example, Stone and Patterson (2005) begin with Max Weber’s interest in bureaucratic hierarchies as an efficient solution to getting things done in the workplace. This led to classical management theory, with its emphasis on using the bureaucracy to achieve objectives, and scientific management theories with their focus on ‘control, ruthless efficiency, quantification, predictability, and de-skilled jobs’ (Stone and Patterson 2005, p. 2). In this context, managers who could organize and direct workers below them in the hierarchy were crucial. There was little emphasis, during this period in the early part of the twentieth century, on the behavioural aspects of organizations. Instead, workers were seen as machine-like, and managers needed only to establish and oversee the correct procedures. By the middle of the twentieth century, management theorists shifted their focus to the factors that motivate people at work and the ways in which managers could harness motivation to achieve results. ‘A new theory of organizations and leadership began to emerge based on the idea that individuals operate most effectively when their needs are satisfied’ (Stone and Patterson 2005, p. 3). In this context, good managers were perceived as those who could do more than structure the work and give orders. They also needed to inspire their workers to lead them.

The tendency to link the characteristics of good managers with those of leaders is thus partly the result of changes in the understanding of the role of a manager. Still, the distinction between the leadership role and the managerial role is widely perceived as the difference between vision and implementation.

These distinctions between leaders and managers apply as well in the health sector. For example, the director of a health district might choose to have an operations director who manages the finances and daily implementation, thus allowing her/himself the freedom to develop strategies and engage diverse actors in a shared vision of the district’s health goals. A hospital, to give another example, needs a manager who with limited finances can organize and implement a detailed schedule of surgeries involving people, equipment, and other resources. However, a hospital also needs a leader who can motivate staff to provide high-quality work in the context of budget restrictions. Sometimes these skills and job responsibilities may exist in the same person, but the nature of management tasks differ from leadership tasks.

In this chapter, we are particularly interested in leadership, rather than management. We do not mean to imply that competent management is not important. On the contrary, the ability to take care of the controlling tasks associated with implementation is crucial to the delivery of programmes and services in public health, and certainly research and funding are needed to improve management in order to strengthen the functioning of health systems (see, for example, Egger et al. 2005). However, the current interest in public health leadership is in itself worth exploring. Public health requires people who can move the agenda in a world dominated by the politics of vested interest groups. It requires individuals who can take scientific evidence and use it to change the direction of policy. This calls for ‘big picture’ skills and the ability to influence people both inside and outside the public health field.

If we are not mainly interested here in management, we are also not only concerned with leadership within organizations. ‘Leadership deals with interpersonal influence, and management deals with acquiring and allocating resources to achieve work, unit or organisational goals’ (Campbell 2013, p. 412). Leadership is, therefore, broader than the leading of employees within organizations. Leadership takes place in all social and political contexts. In public health, leaders are needed not only in hospitals and department divisions, but also in local, regional, and national government, in other related sectors like education and in large- and small-scale settings. For a broader understanding of leadership, we turn next to a review of academic thinking about leadership.

Evolution of thinking about leadership

Research on leadership, like that on management, has evolved over time (Van Wart 2003). More than a century ago, thinking about leadership focused on the inherent personality of the individual leader: ‘This ‘Great Man Theory’ approached leadership capacities as innate, fixed and cross-contextual... the leader as solitary actor’ (Turning Point 2001, p. 14).

This ‘great leader’ theory was deepened, in the first part of the twentieth century, by attempts to identify the key ‘traits’ or ‘attributes’ of successful leaders. Leadership attribute research was still focused on the individual, not the context. This research has continued into the present day and has generated many lists of leader

traits (Zaccaro et al. 2013), including some specific to the health sector, as we show in the next section.

The ‘special individual’ has certainly been invoked in the health sector. For example, Halfdan Mahler, a former head of the World Health Organization (WHO), and James Grant, a former head of UNICEF, were widely thought to have innate leadership qualities that largely explained the success of their agendas. When we interviewed people who had risen to public health leadership positions within their countries and internationally (for an earlier version of this chapter), we noted that leaders are often people who are willing to take risks and to do things that defy convention. However, research and thinking on the question of leadership moved on in the middle of the twentieth century to a ‘contingency’ approach (Van Wart 2003), taking into account the attributes not only of the leader, but also of the followers and the context in which he or she leads, for a more nuanced understanding of leadership success. While acknowledging that ‘the essence of leadership is influence’, this approach accepts that ‘no single leader trait... or style explains leadership in all circumstances’ and focuses instead on ‘the dynamics of leadership—the coming together of leader and follower behaviour in a social and/or organisational context’ (Rumsey 2013a, pp. 1, 2, and 6).

One corollary of the contingency approach is the use of parables or stories to illustrate types of leadership. Stories serve the purpose of simplifying the underlying psychology, sociology, political economy, etc., that might provide theoretical explanations of leadership success. Box 3.1.1 provides some examples, and many others can be imagined. The author argues not only that such stories are explanatory but also that successful leaders use their ‘wisdom, intelligence and creativity to synthesize stories’ that suit their own traits, the context and the followers (Sternberg 2013).

This method of understanding leadership through simplified parables has the value of demonstrating that many different personality types and various character traits may be suited to leadership roles. It also shows that context matters—the level of the leader in the organization, the type and number of followers, the stability of the setting all interact with the leader’s traits (Rumsey 2013b). Among the many variables that may play a role in explaining leadership success are the interpersonal situation, emotional situation, and psychological situation of the leader and followers, as well as the organizational or cultural system of norms and practices and the economic setting (Klimoski 2013).

Simply stated, context presents the leader with any number of situations...; it offers opportunities and constraints. Yet it also should be clear that our current theories or models do not do an adequate job in capturing the various ways that context can, and especially will play out. (Klimoski 2013, p. 283)

Thinking about leadership has thus evolved to acknowledge the great complexity involved in achieving or understanding leadership success. This is a striking change from the earliest ‘great man’ theories:

[C]omplexity leadership [thinking] challenges traditional leadership [thinking] at almost every turn: It challenges the assumptions that individuals are independently responsible for their own failures and successes, or that successful organisations need foster only their human capital (largely ignoring their social capital). It debunks the heroic leader and top-down coordination strategies so central to leadership studies in the 20th century. (Marion 2013, pp. 198–9)

Box 3.1.1 Leadership stories

- ◆ The carpenter—the leader who can build a new organization or society.
- ◆ The CEO—the leader who can ‘get things done’.
- ◆ The communicator—the leader who can communicate with diverse followers.
- ◆ The conqueror—the leader who is going to conquer all enemies.
- ◆ The conserver—the leader who will make sure things stay the wonderful way they are.
- ◆ The cook—the leader who has the recipe to improve the life of his or her followers.
- ◆ The deep thinker—the leader who will make sense out of what is going on.
- ◆ The defender—the leader who will save all followers from harm.
- ◆ The deity—the leader who presents him or herself as saviour.
- ◆ The diplomat—the leader who can get everyone to work together.
- ◆ The doctor—the leader who can cure what is wrong with the organization.
- ◆ The ethicist—the leader who pledges to clean up the place.
- ◆ The lifesaver—the leader who will rescue followers from otherwise certain death.
- ◆ The organizer—the leader who can create order out of chaos.
- ◆ The plumber—the leader who can fix all the leaks.
- ◆ The politician—the leader who understands how ‘the system’ works.
- ◆ The replicator—the leader who is going to be like some past individual.
- ◆ The scout—the leader who can lead followers to new and uncharted territory.
- ◆ The ship captain—the captain of a ship navigating through turbulent times.
- ◆ The turn-around specialist—the leader who can turn around a failing organization.
- ◆ The warrior chieftain—the leader who will lead followers to fight, defensively or offensively, enemies, seen or unseen.

In addition, many contemporary settings have seen developments ‘such as team emphasis, delegation, participative decision-making, flatter organisational structures, self-managed work teams and telecommuting, [that] have rendered leader-centred approaches

obsolete' (Hollander 2013, p. 139). For a leader, achieving results in such a context requires not just the use of skills that will enable individuals to get things done, but also the ability to facilitate disparate group efforts by collaborating and sharing the leadership task: 'we have shifted from a view of leader as sole or unitary actor to a team or community centred view of leadership... from a hierarchical model of leadership into collaborative models' (Turning Point 2001, p. 15). In public health, the collaborative approach may be a necessity, as we illustrate in later sections of this chapter dealing with the complexity inherent in public health practice.

This shift in the way of thinking about leadership—from a top-down model to a participatory one—does not alter the ongoing interest in understanding the competencies and attributes of good leaders. Next we consider these, with an emphasis on health sector contexts.

Leadership competencies, personal qualities, and behaviours

The literature on leadership is replete with definitions and lists of leadership characteristics. In this section, we present two that are particularly thorough and intuitively useful in public health. However, we do so with a couple of caveats. First, research on leadership has not yet presented definitive descriptions, much less definitive prescriptions. As Grint (2002, p. 249) says: 'a science of leadership... has proved incredibly elusive... [and yet] there are indeed plenty of leadership recipes on the market'. In the health sector, this is as true as in other sectors.

Second, there is reason to be concerned that some of the elements of these lists may be 'culture-bound' and thus more accurate in the North American and European settings in which they were developed. Some research has identified culture-specific differences in observed leadership traits and 'many scholars have argued that the effectiveness of a given leadership style varies across cultures in important ways' (Kumar and Chhokar 2013, p. 238). For example, 'participatory' working behaviour may be more relevant in some cultural contexts than others (Flahault and Roemer 1986). In addition, 'directive [as opposed to supportive] leadership seems to be more problematic in individualistic cultures' (Kumar and Chhokar 2013, p. 234). Having said this, there is no harm in advocating the leadership behaviours presented in the two lists in the following sections—such as acting with high ethical integrity, developing an evidence-based vision of the future, and empowering others to work towards public health goals—whatever the cultural context.

Competencies of leaders in health

What do we expect leaders in public health to be able to do? One comprehensive list (Wright et al. 2000) defines the following core competencies of public health leaders:

1. *Transformation*—public health needs and priorities require leaders to engage in systems thinking, including analytical and critical thinking processes, envisioning of potential futures, strategic and tactical assessment, and communication and change dynamics.
2. *Legislation and politics*—the field of public health requires leaders to have the competence to facilitate, negotiate, and

collaborate in an increasingly competitive and contentious political environment.

3. *Transorganization*—the complexity of major public health problems extends beyond the scope of any single stakeholder group, community unit, profession or discipline, organization, or government unit, thus requiring leaders with the skills to be effective beyond their organizational boundaries.
4. *Team and group dynamics*—effective communication and practice are accomplished by leaders through building team and work group capacity and capability (Wright et al. 2000, p. 1204).

In other words, public health leaders need to be able to imagine and create evidence-based change; they need to be able to influence and lobby politicians for support of their public health agenda; they must operate across disciplinary and organizational boundaries; and they must be skilled at developing and working through diverse teams. The authors go on to give more detail about each competency area (Wright et al. 2000). We present a summary in Table 3.1.1. In a practical way, the information in this table answers the question: what do public health leaders do?

Interviews with public health leaders suggest that this is an appropriate list of the types of skills public health leaders need and use in varying degrees. All the leaders we interviewed for an earlier version of this chapter had some vision of an alternate future to which they are committed. Whether it was to improve the health services in a remote location of a country, strengthen the performance of an international public health bureaucracy, or lead research towards better understanding of breast cancer, each had a vision of contributing towards improving the people's health and well-being. Interviewees acknowledged the necessity of working in the political arena, although the extent of political engagement much depended on whether their job allowed them the opportunity to do so. The frustration of not being able to exert influence effectively beyond the health sector was a frequent observation. This confirmed the importance of working trans-organizationally as well as trans-sectorally. Working with ministries of finance was a frequently cited example of doing so. The interviewees acknowledged the critical importance of collaborative work, of building and working in teams. However, it was also suggested by some interviewees that the conventional way in which medical doctors were trained did not necessarily provide them with the skills to work collaboratively in public health teams.

Personal characteristics of leaders

The ability to conduct the change-related, trans-organizational, political, and team-building activities associated with public health leadership seems to rely on a core set of personal qualities. One particularly useful summary argues for a framework of 15 qualities important in a public health leader, broken down into three groups: *personal*, *cognitive*, and *social qualities* (NHS Leadership Centre 2006).

As Fig. 3.1.1 demonstrates, at the core are the five personal qualities of *self-belief*, *self-awareness*, *self-management*, *drive for improvement*, and *personal integrity*. The five cognitive qualities at the top make possible the necessary analytical and procedural skills: *seizing the future*, *intellectual flexibility*, *broad scanning*, *political astuteness*, and *drive for results*. These are then rounded off by five social qualities at the bottom: *leading change through*

Table 3.1.1 Competencies needed by leaders in public health

Creating change	Influencing politics	Working trans-organizationally	Building teams
Visionary leadership Be able to articulate an evidence-based vision of the future and incorporate it into strategy Sense of mission Facilitate the development of a mission, communicate it, and 'model' it through personal behaviour Effective change agent Think creatively and analytically about systems and change strategies, and facilitate dialogue and empowerment of others to take action	Political processes Determine appropriate actions on policy and political issues, organize key actors to cooperate for regulatory and legislative changes, and translate policies into programmes and services Negotiation Mediate potential crises, bargain, and coordinate with key stakeholders Ethics and power Identify and use alliances based on ethical principles Marketing and education Use social marketing and health education to influence key audiences	Understanding of organizational dynamics Assess and develop systems structures based on an understanding of culture and organizational behaviour Inter-organizational collaborating mechanisms Involve key actors and networks across a broad range of organizations and groups in collaborative coalitions Social forecasting Analyse trends and communicate predictions to consortium partners	Develop team-oriented structures and systems Change system infrastructure to encourage innovative, learning teams Facilitate development of teams Empower, motivate, and reward teams Serve in facilitation and mediation roles Negotiate and intervene to help teams function Serve as an effective team member Through own behaviour, 'model' the key characteristics of listening, encouraging and motivating while displaying integrity, commitment, and honesty

people, holding to account, empowering others, effective and strategic influencing, and collaborative working.

The ten qualities associated with 'setting direction' and 'delivering the service' shown as the outer ring of the doughnut in Fig. 3.1.1 can be viewed as another way of presenting the same basic material we have illustrated in Table 3.1.2. But the core personal qualities presented at the centre of the doughnut are worth emphasizing because they represent the personal behaviour of a leader. These core personal characteristics explain *how* leaders are able to do what they do. Self-belief, for example, is a 'positive "can do" sense of confidence which enables [outstanding leaders] to be shapers rather than followers, even in the face of opposition' (NHS Leadership Centre 2006, p. 4). Leaders are also self-aware. They know their own emotions and learn from mistakes (NHS Leadership Centre 2006, p. 13). Leaders demonstrate self-management. They are 'tenacious and resilient' in complex and difficult working environments (NHS Leadership Centre 2006, p. 5). They do not lose control, but manage their emotions (NHS Leadership Centre 2006, p. 14). Public health leaders have a vocation that feeds a 'drive for improvement': 'Outstanding leaders are motivated by wanting to make a real difference to people's health...[by] investing their energy in bringing about health improvements—even to the extent of wanting to leave a legacy which is about effective partnerships, inter-agency working and community involvement [rather than their own reputation]' (NHS Leadership Centre 2006, p. 5). And finally, leaders demonstrate personal integrity: 'a strongly held sense of commitment to openness, honesty, inclusiveness and high [ethical and performance] standards' (NHS Leadership Centre 2006, p. 16).

This NHS Leadership Centre framework of the personal characteristics of leaders is reinforced by consideration of one recent academic review summarizing leader attributes cited in scholarly reviews of leadership (not specifically in health) over many decades (Zaccaro et al. 2013). Among the domains identified are the following (excerpts):

**Fig. 3.1.1** NHS leadership qualities framework.

- ◆ *Cognitive capacities*: general intelligence, judgement/decision-making skills, organizing skills
- ◆ *Social capacities*: social intelligence/sensitivity, communication skills
- ◆ *Personality*: extraversion, conscientiousness, openness, agreeableness, neuroticism/emotional stability
- ◆ *Motives*: dominance, drive/purpose, energy, tenacity/persistence
- ◆ *Core beliefs/self-evaluation*: self-confidence, self-efficacy
- ◆ *Knowledge*: knowledge of the business/sector
- ◆ *Other*: honesty/integrity.

Transactional, transformational, and servant leadership behaviours

In addition to their personal qualities, leaders tend to behave in one of two ways when seeking to accomplish something: They may be ‘transactional’ or ‘transformational’ in their approach (Avolio and Bass 1999). Transactional leadership behaviour uses rewards and punishments deliberately. In contrast, transformational behaviour is more likely to mean presenting a vision of how things could be done differently:

Thus, transactional leadership is based on exchange; for example, in business, this is often financial rewards for productivity, whereas transformational leadership is a process of inspiring people to achieve shared goals through recognizing individuals’ needs, stimulating creative thinking and aligning values between individuals and groups. (Walumbwa and Wernsing 2013, p. 393)

These two ways of behaving are not mutually exclusive. Indeed, in the past two decades, leadership theory and research has focused on a ‘multifaceted’ approach to understanding leadership success, integrating transactional and transformational elements (Van Wart 2003).

Research on leaders in the public sector (including health workers) suggests they are more likely to be transformational in their approach (Alban-Metcalfe and Alimo-Metcalfe 2000). Research on the leadership styles of doctors also indicates that those with transformational behaviours are perceived as more effective leaders and are able to deliver better healthcare results (Xirasagar et al. 2005, 2006). Some may argue that this is likely to be true generally of health sector leaders, but the importance of the distinction could depend on context. Perhaps transactional leaders are needed in certain urgent settings (such as emergency epidemic responses or operating theatres) while transformational leaders are needed in more complex domains (such as influencing changes in health policy). Both transformational leadership and contingent reward leadership have been shown to have positive effects on performance in different contexts, although research does provide ‘evidence suggesting that transformational-leadership behaviour does indeed add some unique variance beyond that provided by transactional leadership’ (Walumbwa and Wernsing 2013, p. 393). However, ‘[c]ross-cultural studies [of] transformational leadership suggest that there are similarities as well as differences about the nature and impact of transformational leadership across cultures’ (Kumar and Chhokar 2013, p. 239).

Finally, leadership research has recently also identified behaviours of the ‘servant leader’—one who takes on an ethical responsibility to his or her followers, to all relevant stakeholders, even to society as a whole (Van Wart 2003). These behaviours include acting with humility, integrity, altruism, and trust while collaborating with and empowering followers (Dennis and Bocarnea 2005; Sendjaya et al. 2008). These behaviours may be particularly relevant in public health. As we discuss later in this chapter, public health leadership is by its very nature about service to people.

Emphasizing the special qualities of public health leaders, as we have done in this section, seems to imply that leaders are somehow born exceptional. But the personal qualities and competencies cited earlier, such as self-knowledge and political skill, might also result from a maturity of experience. Similarly, people may pick up transformational or transactional behaviour as they progress

through their careers. Thus, it seems likely that leadership can be learned, at least in part. But can it be taught? We turn next to that question.

Training leaders

Around the world, isolated initiatives to train health sector leaders have been developed and implemented, often focused on enhancing technical skills or improving workplace interactions. But ‘[p]ublic health has only recently begun to explore the potential of formal leadership education and training’ (Koh and Jacobson 2009, p. 201).

Many training efforts are focused on the traditional attempt to ensure that public health leaders have the epidemiological and statistical skills to understand research and evaluation of interventions and outcomes. The curriculum in most schools of public health is focused on such technical areas and the phrase ‘public health training’ is often used as shorthand for education in epidemiology and its related domains of statistics, demography, etc. In light of the importance of such skills, the Training Programmes in Epidemiology and Public Health Interventions Network (TEPHINET) was established in association with the WHO, the US Centers for Disease Control and Prevention, and the Fondation Mérieux to train public health personnel around the world. ‘These programmes are becoming increasingly recognized as catalysts for strengthening the scientific basis of policy-making through the continuous examination of data’ (Cardenas et al. 2002, p. 196). Now part of the Task Force for Global Health, TEPHINET ‘is a professional alliance of more than 55 Field Epidemiology (and Laboratory) Training Programs with participants from over 80 countries’ (TEPHINET 2012).

In order to be able to analyse trends and articulate a vision of the future, public health leaders clearly need to be able to assess and use the available research evidence. This skill is conventionally believed to be one that can be taught. But what about skills like trans-organizational work and team-building? Can these be conferred on a potential leader by means of a training programme? Some interesting evaluations suggest they can.

Saleh et al. (2004) evaluated training provided by the Northeast Public Health Leadership Institute (NEPHLI) in the United States. Issues covered in the year-long programme include such slightly nebulous topics as building collaborative relationships, group problem-solving, and dealing with cultural diversity. The evaluation results show that the participants clearly believe their abilities were enhanced in the 15 competency areas assessed. In addition, those who had reason to use certain particular skills as part of their work were more likely to perceive an improvement in their competence as a result of training. A key aspect of this training was, thus, the relevance of the topics to the participants’ daily work. There may be, of course, a distinction between the participants’ perception that the training improved their skills and the reality when they apply these skills. Nevertheless, it seems reasonable that those (such as doctors and nurses) whose basic training and earlier work skills are technical medical ones would benefit from training that emphasizes a very different set of procedural skills. For example, in this case, the ‘[t]opics covered included influencing others, measuring and improving public health performance, developing collaborative relationships and partnerships, risk communication, team building, group problem

solving, responding to the needs for cultural diversity and competence, and emergency preparedness training' (Saleh et al. 2004, p. 1245).

Another training programme evaluation sheds some light on the mechanism by which these behavioural skills are transferred to the participants. Umble et al. (2005, 2011a, 2011b) assessed a leadership training programme in which all the members of a public health team participated together in the training. In addition, the training was based on the participants' real work and on typical projects. The results showed improved outcomes with regard to collaborating and networking, key aspects of leadership.

This team training approach seems to have improved the participants' confidence to work collaboratively and to lead a team, as well as improving their practice of these behaviours. The authors conclude from this evaluation that 'networks and collaborative leaders can be developed through education, and that groups thus created can improve services and programmes' (Umbel et al. 2005, p. 642). This approach to bringing together, as a team, leaders who will have to work together to solve public health problems has the potential to work elsewhere. See, for example, a story from the Philippines presented in Box 3.1.2 which shows that training medical, political, and community leaders together fosters the networking skills and builds the very communication links

needed to address public health priorities. The evidence suggests that this is an approach that might reasonably be tried elsewhere.

In addition to formal training programmes, the development of leaders has also been promoted by means of 'mentoring', 'shadowing', or 'coaching' (Turning Point 2001, p. 51). Mentoring is the process by which a more experienced person guides a more junior person with regard to various work- and career-related decisions. It may involve helping the junior person solve problems at work by empathetic listening and feedback. Mentoring may also involve the experienced person giving career advice to the junior.

Shadowing can work with a more senior person either being shadowed or doing the shadowing. In the former approach, a more junior person follows the senior one in his or her job over several months. In this way, learning takes place by observing and participating in the work of an established leader. The latter approach involves a more experienced person shadowing a junior over a shorter period of a day or few days, and then giving constructive feedback on the junior's behaviour and activities at work.

Coaching does not necessarily involve a senior and junior person. A coach may be a specialist psychologist or counsellor who can provide assessment and feedback about skills and practice to a leader or someone wishing to develop leadership skills. Coaches may set goals and tasks for the subject, followed by discussion

Box 3.1.2 Training local teams to be health leaders in poor communities: a case from the Philippines

The Philippines provides an innovative approach to leadership for the health needs of the most deprived and vulnerable populations. Begun in 2002, the Leaders for Health Program (LHP) was predicated on the understanding that health professionals must work in concert with political and community actors if basic health problems are to be addressed in low-income communities. This 'Tri-Leader' approach brought together the community doctor, the mayor, and a local community leader and trained them, both individually and as a team.

To address the need that medical leaders understand and are able to use evidence to inform policy, doctors received postgraduate training resulting in a Master in Community Health Management. Recognizing that the local political and community leaders often did not have an advanced level of education, the programme created a certificate course in community health management tailored to them, but paralleling the master's training provided to doctors. Joint workshops and training sessions were also held for the tri-leaders together. In addition, all three benefited from coaching and mentoring from a more experienced leader of their own category from another part of the country. Once this team began to identify priorities in its locality, the LHP provided assistance in identifying donors for specific interventions. For example, some communities invested in sanitation and clean water systems. One community established a local pharmacy; another invested in a boat for emergency transport of patients.

By taking this innovative approach to leadership—one that recognizes the importance of joint leadership in the medical, political, and local communities in order to address public health needs—the LHP has been able to demonstrate greater success than other initiatives that focus only on placing trained doctors in low-income areas. Its success would seem to be due to the programme's understanding of the complexity of health systems. For example, addressing water-borne diseases properly requires sanitation systems, and sanitation systems cannot be built without political support. In addition, the programme's training of doctors together with mayors and community leaders helps doctors to see beyond the narrow biomedical domain to the broader political and sociological setting in which public health problems must be tackled. One mayor reported that earlier attempts to post doctors to his village were unsuccessful because the doctor was perceived to be making demands arrogantly of a resource-poor community, rather than working with the community to reach a common understanding.

A cost analysis of the programme found that the cost per person for the close to 1 million beneficiaries in the 36 towns that participated in the LHP over its initial 4-year period was Philippine pesos 60 or USD 1.50 per year. Furthermore, for every peso invested in the programme as grant, the local government and other national government partners were able to raise a counterpart share of Philippine pesos 1.27. LHP therefore stimulated the mobilization of local resources for health system development. Most of the graduates of the LHP have continued to work in their posts. Some joined various units of the Department of Health, the US Agency for International Development and Médecins Sans Frontières, showing a remarkable record for retaining health professionals in places of need. As a result of the LHP's success, its expansion to other local government units is now being considered as part of the national effort to strengthen local health systems.

sessions designed to help him or her learn from the experience. Peers may sometimes coach one another, although this may be more successful when the peers are not in direct competition with one another (Turning Point 2001, p. 52).

Among the leaders we interviewed, mentoring and shadowing experiences occupied a prominent place in their development. Many cited their mentors with great fondness and appreciation. And there were instances when more than one mentor was acknowledged by a leader.

It appears, then, that the training and development of leaders is possible: 'You cannot transform a person with no talent into a successful collaborative leader, but you can take a rough diamond and polish it. You can hone the skills of those who have some aptitude for it' (De Meyer 2011, p. 59). The old assumption that leaders are born with innate skills that cannot be taught, no longer seems true. Waiting for great leaders to emerge is not necessary. Instead, the health sector can seek to train, develop, and promote leaders. Although 'we have only barely scratched the surface in our efforts to build a science of leadership development', there is now evidence that training can build specific leadership skills (Day 2013, p. 76). And, equally importantly, it is clear that 'the role of leader identity construction is emerging as a central process in the effective development of leaders' (Day 2013, p. 87). That is, as a person begins to think of him/herself as a leader, he/she is motivated to learn more about what to do and how to act as a leader.

In this chapter so far, we have reviewed the concepts behind leadership studies and research and considered the matter of training and developing leaders. But, beyond this, how does leadership work in the gritty, very real world of day-to-day public health work? In the next section, we reflect on the practice of public health leadership, using real examples.

Leadership in health today

Acknowledging and addressing complexity—putting theory into practice

Health systems are complex. In all countries, health systems are broad and multisectoral. They involve complicated interactions among politics and policy-making, financing, training and education, and public and private organizations. It is not easy to define where public health activities end: a large manufacturing company may employ someone to conduct health education with its staff, just as the government might engage outreach workers to do the same with villagers. In the context of a very complex system that extends far beyond the boundaries of any one organization, it is not possible to 'manage' things in a mechanical way (Plsek and Wilson 2001). Imposing simple managerial or technical-medical solutions on a public health problem will not solve it. Indeed, if technical and mechanistic solutions were all that were needed to address public health problems, we would not need leaders. Instead, the complex, multi-organizational, and team-based nature of public health work requires people who can inspire others to achieve results working through the complexity.

The leaders we interviewed voiced both enthusiasm and frustration with the work they were engaged in. While they spoke of positive gains in their work, they also spoke of conditions beyond their sphere of influence, and of existing economic and political forces far beyond their personal or their organization's capacities to change. Despite these difficulties, hardly any interviewee suggested

that they should give up. Instead they seemed to understand that their mission of service will come up against problems and dilemmas inherent to this complex world. As Binney et al. (2005) note:

[L]eaders are able to use all their intelligence, senses and experience to connect with others and make sense of the context... They are able to tolerate the complexity of events and people and not rush to simple-minded solutions that don't make sense. Their focus is on both long- and short-term issues. (Binney et al. 2005, p. 93)

Let us look at four examples of complexity faced by public health leaders.

First, consider the relationship between disease and poverty manifest in epidemics. In Manila, there are perennial outbreaks of diarrhoea in the urban slums because residents illegally tap water lines causing contamination of water. When such a water-borne outbreak occurs, the water company needs to step in. It removes the illegal connections, repairs leaks, flushes out the contamination, and increases the chlorination levels in the affected water lines. Public health authorities undertake epidemic investigations and related measures to treat the sick and prevent the infection from spreading in households.

While appearing to be a local issue, this phenomenon is a microcosm of a global problem described in the text of a WHO poster that reads: 'For the first time in history, more than half of the world's population lives in urban settings. Three billion people live in cities. One billion people live without access to safe drinking water' (WHO n.d.).

What can be done to prevent perennial outbreaks of water-borne diarrhoea in urban slums caused by the illegal tapping of water lines? How could a public health leader deal with this situation in order to find a longer-term answer to it?

Second, consider the relationship between disease and people's lifestyles. The association between smoking cigarettes and cancer is now well established. In 2003, the World Health Assembly ratified the Framework Convention on Tobacco Control, which urged member states to undertake a variety of actions in order to reduce smoking among their populations (WHO 2003). Despite scientific advances leading to a better understanding of the ill effects of smoking and the aforementioned landmark global agreement, the prevalence of smoking among youth and women is on the rise in many countries. And while some countries now have legislation to ban smoking in public places, governments in many countries seem not to be doing enough to discourage and reduce smoking among their citizens.

How could the public health leader, such as a city health officer, deal with the situation if the city mayor or the city council have not enacted any measures to stop smoking in public places?

Third, consider the relationship between a disease, the necessary medicines for its treatment, and the commercial interests involved in making those medicines accessible to the people who need them. HIV/AIDS has become a drag on social and economic development. Life expectancies have been shortened drastically in many countries because thousands of people succumb to AIDS at an early age. Large numbers of AIDS orphans are overwhelming the capacities of families and societies to provide and care for them. Antiretrovirals exist, but they are expensive and still inaccessible to millions of infected people.

How could a public health leader, such as a Minister of Health in a country with a large burden of HIV/AIDS, take steps to provide antiretrovirals for thousands of citizens with the disease?

Fourth, consider the relationship between people's reproductive choices and the prevailing traditions, moral views and teachings of religious institutions. Faced with unwanted pregnancies, women may seek abortions. Often, these abortions are conducted under surreptitious and illegal conditions, placing women at high risk of life-threatening bleeding and infection. Legalizing abortions will result in better regulation of the practice of abortion, thereby making the procedure less risky.

How does a public health leader deal with a situation where the scientific evidence shows that decriminalizing abortion prevents maternal deaths from sepsis, but his moral beliefs run counter to implementing such a change?

These four examples are only a few of the many complex issues that public health leaders face. As they bring themselves to lead under these challenging circumstances, their personal qualities, technical, and social competencies will be tested. It can be overwhelming to lead in such complex situations, and leaders must be realistic about what they and their organizations can accomplish.

Principled leadership

In the face of such challenges, leaders need more than the attributes described earlier to help them succeed. Also vitally important is a set of principles that can serve as a guide to thought and action. Where would public health leaders find such a set of principles? We offer five principles derived from the WHO Constitution (WHO 1946; see Box 3.1.3):

1. Commitment to the vision of total human development.
2. Commitment to empowering the poor and the vulnerable with knowledge and opportunity.
3. Pursuit of evidence and truth.
4. Commitment to fairness and equity in the provision of adequate health and social measures.
5. Trustworthiness and public accountability.

Applied singly or in varying combinations, we submit that these principles provide the foundation and inspiration for public health work.

Let us examine how these five principles might help a public health leader address the four complex challenges set out previously. In the first challenge discussed earlier, public health leaders are asked to find a longer-term solution to control water-borne outbreaks of diarrhoea in urban slums. Principle 1, which calls for commitment to total human development, urges these leaders to think beyond epidemic control. It challenges them to address the problem of urban slums to tackle the social determinants of water-borne outbreaks. This is exceedingly complex and difficult. However, where Principle 1 is combined with Principle 2, more durable solutions have been found. The experience of Gawad Kalinga in the Philippines demonstrates how a movement to eradicate urban slums has improved the health of people in such communities and in the process has prevented the perennial occurrence of outbreaks there (see Box 3.1.4). By addressing the land and housing issues at the root of urban slum communities, Gawad Kalinga was able to build low-cost houses and proper water supplies for the families previously dwelling in slums.

Principle 5, trustworthiness and public accountability, is applicable to the second challenge. Big business interests protect and

Box 3.1.3 WHO Constitution

THE STATES Parties to this Constitution declare, in conformity with the Charter of the United Nations, that the following principles are basic to the happiness, harmonious relations and security of all peoples:

- ◆ Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.
- ◆ The enjoyment of the highest attainable standard of health is one of the fundamental rights of every human being without distinction of race, religion, political belief, economic or social condition.
- ◆ The health of all peoples is fundamental to the attainment of peace and security and is dependent upon the fullest co-operation of individuals and States.
- ◆ The achievement of any State in the promotion and protection of health is of value to all.
- ◆ Unequal development in different countries in the promotion of health and control of disease, especially communicable disease, is a common danger.
- ◆ Healthy development of the child is of basic importance; the ability to live harmoniously in a changing total environment is essential to such development.
- ◆ The extension to all peoples of the benefits of medical, psychological and related knowledge is essential to the fullest attainment of health.
- ◆ Informed opinion and active co-operation on the part of the public are of the utmost importance in the improvement of the health of the people.
- ◆ Governments have a responsibility for the health of their peoples, which can be fulfilled only by the provision of adequate health and social measures.

ACCEPTING THESE PRINCIPLES, and for the purpose of co-operation among themselves and with others to promote and protect the health of all peoples, the Contracting Parties agree to the present Constitution and hereby establish the World Health Organization as a specialized agency within the terms of Article 57 of the Charter of the United Nations.

promote the sale of cigarettes. Some of these business interests may even have philanthropic projects which benefit the public, such as grants to educational institutions or youth scholarships. It can be convenient for public health leaders to take the path of least resistance and not call for a ban on cigarettes in public places. Principle 5 calls on public health leaders to be faithful to their calling of safeguarding public health despite the odds against them. In this respect, they are trustworthy and accountable to the public for their actions, even if some of their actions may be politically unpopular. There are public health leaders who have unstintingly used the built-up scientific evidence on the ill effects of smoking

Box 3.1.4 Gawad Kalinga: improving well-being by empowering the poor

Gawad Kalinga (GK) means to ‘give care.’ GK is a non-profit foundation whose vision for the Philippines is a slum-free, squatter-free nation achieved through a strategy of providing land for the landless, homes for the homeless, and food for the hungry in order to attain dignity and peace in poor Filipino communities.

What started in 1995 as a daring initiative by a faith-based organization to rehabilitate juvenile gang members and help out-of-school youth in a large squatters’ relocation area in Metro Manila, has evolved into a multisectoral movement supported by local and multinational corporations.

GK works actively in the poorest urban areas and concentrates on providing decent homes and the resources necessary for self-sufficiency. It seeks a holistic approach to poverty alleviation that includes various components: the provision of basic healthcare, community organization, livelihood programmes, and values formation. Even before a GK house is built in a slum community, issues of land ownership, capital for house materials, participation of the residents in the construction of the houses, eventual ownership of the built houses, and community building are considered and dealt with. Complex social dynamics are involved in dealing with these varied issues.

Part of the current success of GK is attributed to this stewardship component which integrates leadership building into the GK communities. Every GK village has a Caretaker Team comprised mainly of resident volunteers who undertake specific responsibilities like assisting in resolving conflicts, ensuring the proper management of the resources for constructing the houses, and seeing to it that the GK standards for a well-organized community are maintained.

GK was given the Ramon Magsaysay Awardee in 2006 and the Skoll Award for Social Entrepreneurship in 2012.

to persist in the campaign to fight against cigarette smoking. The recent implementation in Australia, for example, of plain cigarette packaging with antismoking messages and photographs showing the ugly effects of cigarette smoking are a breakthrough in the fight against the tobacco industry (BBC News Asia 2012).

Principle 4, commitment to fairness and equity, may be applicable in the third challenge. In the face of the complex issues concerning the way in which pharmaceuticals are produced, sold, and distributed, answers must be found to address the lack of access to medicines by millions of people. The solutions to these imbalances are not straightforward. They involve the dynamics of the domestic and international market for medicines. Where patents for new medicines are involved, there are international agreements that govern the production and marketing of generic copies during the patent term. In addition, negotiations with pharmaceutical companies have resulted in agreements to sell critical drugs at

reduced prices in developing countries. There are concerns that pharmaceutical companies may stop investing in research and development of drugs that might benefit the poorest countries, leading to calls for a new model for funding research into new drugs. Notwithstanding these complexities, public health leaders, seeking to broaden their populations’ access to medicines, are persevering with the global and domestic politics needed to accomplish this goal.

The application of Principle 3—the pursuit of evidence and truth—is relevant to the fourth challenge and may guide a public health leader to advocate for the legalization of abortion, explaining that this policy significantly decreases maternal deaths. But those against abortion will resist this evidence, taking the view that no law can justify terminating the fetus in early pregnancy. The leader may persist, providing other evidence, namely that limiting access to legal abortion is not associated with lower abortion rates. But people’s beliefs and values vary, and these beliefs may dominate evidence in policymaking. In the Philippines, while a reproductive health bill was recently signed into law mandating government funding for contraceptives, legalization of abortion remains politically unacceptable as public policy (Sandique-Carlos 2012). So, even as public health leaders pursue the evidence to justify health interventions, there may be historical and social considerations that override it. Public health leaders, whatever their moral beliefs, will have to confront those realities as they continue to present the evidence and promote equity for women.

These four complex challenges illustrate the broad range of skills required by successful public health leaders. As we showed in Table 3.1.2, the competencies needed extend far beyond medical and epidemiological skills to incorporate the systems thinking and political skills needed to influence change.

The path to leadership

You too can become a public health leader—but how can you develop the personal qualities and competencies needed to do so?

There are many paths to leadership. The public health leaders we interviewed first entered the profession with a strong desire to serve. Through the course of their careers, they were exposed to circumstances that deepened their commitment. Frequently, they sought out challenging circumstances in which to gain much needed experience. They travelled, engaged in development work, often involving poor countries and communities. In the course of this exposure, they took up more advanced public health studies, perhaps did some research, wrote articles in scientific journals, or managed a healthcare facility. Some had long periods of service in their own country before being exposed to international work. For others, international exposure came early, usually through some clinical or public health training abroad.

Some of our interviewees moved into public health after years of working in the clinics, practising a speciality like paediatrics, obstetrics, or surgery. Others came into positions of leadership through the field services, rising through a public health organization, or a non-governmental organization. Others were involved in academia, teaching and research, consulting, or working with a development agency. Public health leaders could also have been involved in politics. Or they could once have been cause-oriented activists, involved in issues such as HIV prevention and primary healthcare.

Mentors play a significant role in the development of the public health leader. Nearly everyone we interviewed cited people significant to their career at various stages. One public health leader we spoke to for this chapter put it this way: ‘A leader creates a path for others to succeed’. Another interviewee mentioned how his boss and mentor encouraged him and other young people in the organization to think up and explore new ideas.

Central to the growth and development of the public health leader are the years when he/she developed the personal qualities of self-awareness, self-belief, and self-management. In those we spoke to, there was the strong conviction that their involvement in public health was imbued with higher purpose and even that they were instruments of a higher power to do good work. Certainly, the sense of ‘other-orientatedness’ was quite a major motivation infusing the leaders’ sense of service. Among those interviewed, none said that money was a strong motivating factor for the choice of a public health career. A desire to continue learning new things was often mentioned as a source of great satisfaction. One public health leader emphasized the necessity to listen and learn from others before making decisions.

We encourage potential health leaders of tomorrow to forge their ‘path to leadership’ on three fronts:

1. Know your guiding principles.
2. Seek mentors and aim to learn from every situation you face.
3. Pursue leadership, not the leadership position.

Know your guiding principles

The WHO Constitution—drawn up in a fertile climate of unprecendented hope by international leaders in every field—can be distilled into fundamental guiding principles that are central to a public health leader’s work. In reality, individual context, culture, and background dictate that each leader will interpret these principles slightly differently and will complement them with additional principles derived from their personal philosophy of life. Together, this collection of principles will serve to give focus and meaning to the health leader’s work.

These principles must be embedded firmly in the mind. Leaders need to think and act on their feet. Unless one is sure of one’s principles, in a time of crisis—with perhaps many lives at stake—panic and uncertainty might take over. There will not be time to think about remembering your principles when the need to make a decision is immediate. For this reason, taking the time to understand what guides you—to ‘know thyself’—is invaluable. Take time to think about what it is that guides you, or what you would like to guide you.

Seek mentors and aim to learn from every situation you face

Both the literature on leadership and the practical experience of today’s health leaders underline the crucial importance of mentorship in the development of the complete public health leader. To achieve self-improvement, being prepared to learn from superiors, fellow colleagues, friends, and public figures is essential. But how does one ‘obtain’ a mentor?

There is no fixed prescription for mentorship. By its very nature, it is a personal arrangement between two parties. Some programmes encourage their participants to go out and seek a mentor

other than their direct supervisor—someone they admire, probably working in their vicinity—and to invite them to act as a mentor. Following this, an arrangement can be struck that is convenient and suitable to the mentor and the mentee. The mentoring relationship could be formal and structured, with regular meetings and log book entries; or it could be more informal and sporadic, with the occasional chat over coffee or e-mail correspondence.

The opportunity should be taken for the mentor to impart advice, the mentee to report on recent events, and for both to share thoughts on work and even wider aspects of life, particularly if relevant to a career in health and leadership. Ideally, a mentoring relationship should be mutually beneficial, with both parties learning from one another, enriching their understanding of their work and purpose.

Pursue leadership, not the leadership position

Looking back to the beginning of this chapter, at the distinction between leadership and management, it is clear that whereas to exercise management it is necessary to be in a management position, the skills, characteristics, and competencies of leadership can be practised regardless of one’s position in a hierarchy. One pursues leadership by steadily inculcating in oneself the personal qualities, competencies, and principles that make up a true leader. One does not acquire these necessary attributes and skills simply by ascending to a leadership position, often via political patronage, especially if one lacks adequate preparation. Study, training, reflection, exposure, and experience are all elements of this preparation. Thus, as one’s leadership traits flourish, the time will come when one is ready to assume a leadership position. Leadership should be sought in this way from day one of any career and hence, any strong public health organization should encourage leadership development at all levels.

When does one know that he/she is ready to take up a position of leadership? The trajectory of an individual’s path to leadership can rise steeply or gently. It is one’s willingness to step forward, given one’s self-awareness and knowledge of the prospective job, however incomplete, which might mark a person’s readiness to lead. A potential leader will almost always be selected by having already demonstrated leadership and by showing readiness to lead. In deciding if one is ready to assume the responsibility of a public health leader, it of course helps to discuss the opportunity with mentors, co-workers, and family members.

Once in a leadership position, the leader must keep learning. Mistakes will be made, disappointments and conflicts will occur. The strong face of leadership is well observed, but how do top health leaders deal with themselves during the dark hours, when the tasks seem overwhelming and when results fall short of expectations? It is often said that in these situations, leaders dig deep into themselves to find internal resources of strength. The capacity to affirm self-belief and overcome self-doubt is an important ingredient in surviving the difficult times; but it is also true that the leader turns outward to others for strength. One leader whom we interviewed emphasized that she turned to her community for rejuvenation and inspiration. ‘We hold on to each other’, she said. Others turn to family members or colleagues for support. And there are many who through prayer and meditation, turn to their faith or guiding principles to find inner strength.

How can a leader know how he/she is doing? A leader can listen closely to what the boss, spouse, colleagues, friends, constituencies, or even opinion surveys say. Or a leader may listen inwardly reflecting on thoughts, actions and lived experience in the midst of complexity, adversity, and uncertainty. Sometimes, institutional awards and honours may bestow recognition. By learning to be truly honest with oneself and seeking objective, constructive, and critical feedback from others, a leader can begin to find an answer to this question and sustain self-improvement. We find that the unsolicited compliment like ‘Thank you for your fine example’ or the gentle rebuke ‘Perhaps if you had done it this way...’ provide invaluable inputs to a leader’s self-awareness.

We hope that the reflections presented here will help to direct the interested and motivated reader in tracing his/her own ‘path to leadership’. Before bringing this chapter to a close, and as a final pointer for those wishing to serve the needy through public health leadership, we might look at things from another perspective. Instead of asking ‘What do I need in order to become a health leader?’ perhaps we should ask ‘What kind of leader does the world need?’

Getting the public health leaders the world needs

We need public health leaders everywhere and at every level of the health system. However, good leaders are most needed in places where people are poor and suffering simply because there is such a scarcity of them there. Committed and effective leaders often provide the vision and impetus to mobilize people and resources in needy areas. How can the international health community help developing countries develop the needed leaders? A good starting point is to aim at strengthening educational institutions, which can provide relevant, team-based training. Schools of public health have an important role to play (Colgrove et al. 2010). Helping governments and their partners to improve public health working conditions, including financial and non-financial incentives, will also help to attract and retain talented people. From an international perspective we can work towards empowering nations to do this self-sufficiently, strengthening their own frameworks for leadership. Health leaders have used the term ‘capacity release’ in reference to this kind of endeavour (Chan 2007). It must be stressed that training programmes are only one component of a comprehensive approach that should include strategies to retain promising public health workers and sustain the idealism of leaders who are prepared to venture forth to places of hardship. We must encourage and support them to stay where they are most needed. Examples of work being done on this include the WHO framework on training leaders and managers (Egger et al. 2005) and related work to strengthen leadership at all levels of the health system.

The challenge now is particularly great. We have not yet established systematic ways to develop public health leaders, while the context is becoming ever more complex. To address the social determinants of health, confront the ongoing communicable disease burden as well as the rising burden of non-communicable diseases, and truly ensure ‘health in all policies’ will require

devoted and determined public health leaders at all levels of society and in all sectors.

Conclusion

As we reach the end of this chapter, here are some key points for the aspiring leader:

- ♦ Leadership is displayed in a complex interaction between the leader, the followers, and the context. Parables about different types of leadership illustrate the diversity of contexts and behaviours that may be associated with successful leadership.
- ♦ In the face of ever-increasing complexity, public health leaders are needed to prevent, treat, and eliminate disease and promote the health and well-being of all people. Such leadership can be developed by local, national, and international actors.
- ♦ Public health leaders demonstrate personal qualities and skills, underpinned by fundamental principles, which enable them to influence actions and results. The constant manifestation and practice of these attributes and beliefs is a continuing challenge in a leader’s job and career.
- ♦ Each ‘path to leadership’ is unique and very personal. However, exposure, training, mentors, and guiding principles all help in the development of leadership qualities in individuals who aspire to lead. These should be sought by anyone interested in serving as a public health leader.

The pursuit of leadership should ennoble the mind and the heart of those who aspire to it. It is a dignified and never-ending quest. We bid the reader all success.

Acknowledgements

The authors would like to thank Amimo Agola, Anand Kurup, Chadia Wannous, Christine Lamoureux, Claudia Vivas, Delanyo Dovlo, Dick Chamla, Francis Omaswa, Guangyuan Liu, Helen Robinson, Lealou Reballos, Maria Eufemia Yap, and Miriam Were, among others, for their insights into the issues of leadership in public health. The authors would also like to acknowledge the contributions of Carmen Dolea, Daniel Shaw, and Joanne McManus to an earlier version of this chapter.

Ethical principles and ethical issues in public health

Nancy Kass, Amy Paul, and Andrew Siegel

Medical ethics, bioethics, and the emergence of public health ethics

While some cite the Hippocratic Oath as the first articulation of moral duties of physicians, and others cite John Gregory or Thomas Percival as giving birth to medical ethics, codes and teachings about moral duties of physicians have existed for hundreds, if not thousands, of years (Percival 1985; McCullough 1998). Medical ethics focuses primarily on physicians' interactions with individual patients and is the focus of significant scholarship. The American Medical Association has longstanding codes of medical ethics, and instruction on medical professionalism is nearly universal in US and Canadian medical schools (Kao et al. 2003). The American Association of Medical Colleges requires that principles related to medical ethics should be taught in medical core curricula (Allen 2007); the UK General Medical Council requires medical schools to teach medical ethics; and the Medical Council of India requires students to 'observe medical ethics' as part of exemplary behaviour (Ravindran 2008).

Bioethics emerged more recently, with a broader focus. 'Bioethics' as a field arose in the 1960s and 1970s (Walter and Klein 2003) arising from questions of resource allocation, moral questions raised by new reproductive and genetic technologies, a growing patients' rights movement, and a lack of oversight in human subject research. Important scholarship grew, and a national commission was convened in the 1970s to examine questions of human research ethics. The National Commission drafted the Belmont Report (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1979) delineating three ethics principles for human research—beneficence, respect for persons, and justice. This early work in bioethics not only went beyond the individual doctor–patient dyad but also informed public policy.

Bioethics ignited. Centres were created, journals started, meetings convened, and professionals from various disciplines started calling themselves 'bioethicists'. The three 'Belmont principles' became the foundation for a widely used bioethics text (Beauchamp and Childress 1979). While some suggested alternative approaches, 'principlism' remains a widely used framework for healthcare and research ethics (Clouser 1995; Jonsen 1995; Pellegrino 1995), and Belmont principles were adopted for the Council for International Organizations of Medical Sciences (CIOMS) international ethics guidelines (CIOMS 2002).

Early framers of these principles suggested no principle, *a priori*, should have moral superiority over any other (Beauchamp and Childress 1979). Nonetheless, issues animating bioethics early on—the need to tell patients and research participants the truth and the right to refuse medical care or research participation—were ones where respect for autonomy, perhaps given too little moral attention previously, was given pre-eminent moral status (Callahan 1984; Pellegrino and Thomasma 1988; Steinbock 1996). Informed consent, an application of the autonomy principle, became a hallmark of the new bioethics. Codes of ethics for clinical practice, which previously focused on not harming patients, added requirements to respect patients' right to decide about their own care (American Medical Association 1990).

The subfield of *public health ethics*, articulated as such, did not appear significantly in the literature until the 1990s, although Marc Lappe had a chapter 'Ethics and Public Health' in the 1986 Maxcy-Rosenau text *Public Health and Preventive Medicine* (Lappe 1986).¹ This chapter outlined core public health ethics challenges: fair distribution of resources, rights of individuals versus groups, and promoting efficiency while recognizing the 'special standing of those who are disadvantaged in terms of their health status' (Lappe 1986, p. 1875). Moreover, Lappe asserted that whereas medical ethics is more concerned with individual autonomy and duties of single health professionals, public health ethics focuses more on equity and efficiency. Lappe suggested individual rights can be compromised for community interests, but only with proportionality—an intervention's benefit must outweigh its harm, and the absolute level of infringement must be minimal. Related, since many public health programmes do not grant individuals right of refusal, there must be evidence that programmes will provide the good promised. He suggested an inevitable tension between utilitarianism and justice with an ethic of public health capturing the urgency for efficiency, while recognizing the special standing of those in greatest need.

An additional exception from this early history is Dan E. Beauchamp's work, suggesting social justice and communitarian traditions should drive public health (Beauchamp 1976b). While public health practitioners had recognized, for more than a century, the relationship between social conditions and health (see Fee 1977),² Beauchamp's work suggested a new idea *within bioethics* that exclusive attention to individual interests, particularly through market justice, will hinder protecting the public's health. Rather, public health should 'require thinking about and

reacting to the problems of disability and premature death as collective problems of the entire society' (Beauchamp 1976b, p. 9).

Furthermore, Beauchamp challenged bioethics to see public health as furthering community interests in terms of shared commitments we have to one another. Through collective actions in health and safety, for example, we share commitments to the common life (Beauchamp 1985, p. 34). While Beauchamp did not use the words 'public health ethics', his work is foundational in putting forward the idea that public health has its own set of moral priorities.

By the early 2000s a need for a more structured way to examine ethics issues in public health surfaced, and literature examined how public health ethics issues differed from those in medicine or other areas of bioethics. In 2001 and 2002, four articles were published defining the territory of public health ethics and/or offering tools and frameworks for its analysis (Kass 2001; Callahan and Jennings 2002; Childress et al. 2002; Roberts and Reich 2002), suggesting public health ethics requires identifying programme goals, determining effectiveness, minimizing burdens, proportionality, furthering social justice, and ensuring procedural justice. Publication of the first code of ethics by the American Public Health Association, an organization that had existed since 1832, followed in 2002 (*APHA Code of Ethics*; American Public Health Association 2002).

Ethics and health promotion

In the 1970s, several scholars began addressing the degree to which governments should regulate personal behaviour to promote public health. While many of the discussions were influenced by John Stuart Mill's view that government restrictions on an individual's liberty are justified only to prevent harm to others (Mill 1869), debates ensued over whether interventions to improve the health of the person targeted could be morally acceptable. Daniel Wikler suggested that promoting certain lifestyles conveyed a set of moral values when 'It is not self-evident that this vision of a safe society, with its lack of immoderation, stress, and risk-taking, is to be favoured over others whose constitutive elements have incidental adverse effects upon health' (Wikler 1978a, p. 231).

Edmund Pellegrino, one of the 'fathers of bioethics', described an ethics of prevention (Pellegrino 1981). Preventive interventions, he suggested, ranged from more voluntary approaches like health education to increasingly less voluntary ones like opinion manipulation through mass media, tax and insurance incentives and disincentives, and legal prohibitions in the name of what some consider to be 'the good life', highlighting that we are forced to make decisions about what constraints we will accept to further the common good.

Faden and Faden, similarly, described interventions ranging from facilitation to persuasion to manipulation to coercion, arguing the acceptability of different approaches rests on how rational and resistible they are (Faden and Faden 1978). Described here, to be cited frequently throughout future public health ethics writings, was the concept of *proportionality*: the burden posed by (particularly non-voluntary) interventions should be low and benefits high. As such, incentives should be favoured over disincentives, education favoured over manipulative messages, and government intervention ought not occur without considerable evidence about effectiveness.

The Society of Public Health Educators' code of professional ethics went further, calling voluntariness the *only* acceptable approach, suggesting health educators should 'empower individuals to adopt healthy lifestyles through informed choice rather than by coercion (Society for Public Health Education n.d.).

Purely voluntary interventions do not always work, however (Glanz et al. 1997; Roter et al. 1998), and the question for ethics scholars became whether or under what conditions more controlling interventions were acceptable. Furthermore, since governments would be implementing stricter measures, how could one ensure their agenda related to public health rather than politics? (Faden 1987). Involuntary measures also assume 'a benign, wise, and responsive government, something history finds singularly rare' (Pellegrino 1981, p. 375).

Dan Beauchamp suggested shifting focus from the degree to which governments can regulate individual behaviour to, instead, the legal authority of public health to regulate behaviour of those marketing and distributing harmful products (Beauchamp 1976a). Wikler similarly suggested that if outside influences encourage an individual to alter his or her preferences unknowingly, this diminishes the autonomy with which those choices are made (Wikler 1978b). Coercive measures may be needed to control the manipulation of messages that run counter to the interests of public health.

The rise of chronic disease has more recently shifted the focus of public health ethics back to the acceptability of different types of behavioural interventions or public policies designed to influence behaviour. The high burdens of tobacco-related illness, injury, obesity, and diabetes have prompted interventions that target environmental, behavioural, and lifestyle determinants. In obesity prevention, for example, public health ethics must consider the justifiability of government action to restrict access to unhealthy products such as sugar sweetened beverages in various programmes or institutions as well as the effects such proposals would have on morally relevant values such as liberty, privacy, and fairness. Ethics debate surrounds whether all consumer choices constitute protected liberties, and when, if ever, restrictive policies are justifiable absent direct threats to others.

Infectious disease and public health ethics: HIV and pandemic preparedness

HIV/AIDS

Few challenges have forced examination of ethics and public health as much as HIV/AIDS. Multiple public health ethics tensions surfaced, from societal rights versus individual liberties to justice and healthcare access, and arose in core functions of public health: surveillance, disease reporting, containment, and resource allocation. As policymakers navigated tough decisions, much bioethics literature emerged, influencing what would soon be called public health ethics. Arguably, it was HIV that introduced many bioethics scholars to the world of public health.

In 1983, the Public Health Service (PHS) recommended that gay men be discouraged from donating blood (Centers for Disease Control (CDC) 1983), and soon policy documents and individual scholars examined ethics in HIV policy (Bayer 1983; Institute of Medicine 1986; Presidential Commission on the Human

Immunodeficiency Virus Epidemic 1988). Fear and uncertainty precipitated proposals from tattooing infected persons to full quarantine that were highly restrictive while having little evidence of efficacy. Despite almost uniform rejection from bioethics and legal communities (Gostin and Curran 1986; Koop 1986; Macklin 1986; Musto 1986; Porter 1986), policy proposals continued to recommend exclusion of HIV-infected persons from employment, housing, insurance, and school. Bioethicists jumped into the fray to help articulate appropriate public health response and put forward ethical requirements for new screening programmes (Bayer et al. 1986; Childress 1987; Gostin and Curran 1987; Gostin et al. 1987; Hunter 1987; Bayer 1989), cognizant of the tension between potential public health benefits and concerns of exposing at-risk individuals to stigma with no treatment in return.

HIV renewed interest in the ethics of other tools of public health with calls for mandatory HIV reporting, contact tracing, and partner notification. Proponents suggested mandatory reporting would improve understanding of the disease and target education and potential treatments. Critics argued education and treatments could be provided without reporting, which was an unjustified invasion of privacy, particularly when strong antidiscrimination laws did not exist; concerns existed that at-risk individuals would avoid testing, fearing consequences. Support for mandatory reporting increased when treatments became available. HIV stimulated ethics debate in almost every area of public health including health education, duty to treat, resource allocation, access, and financing. While the phrase ‘public health ethics’ was not yet used, the foundation of the field had been laid.

Pandemic preparedness

The re-emergence of pandemic disease in the 2000s pushed public health ethics thinking to modify frameworks for the pandemic context. While the infectious nature of pandemic flu raised familiar tensions between individual interests and population health, the urgency and potential for insufficient resources highlighted additional challenges. Avian flu and severe acute respiratory syndrome outbreaks, for example, were met with insufficient healthcare workforce, vaccine shortages, and complex global governance challenges when pandemics crossed borders, raising questions of healthcare worker obligations, fair resource allocation, and justifications for restricting liberty interests (Gostin 2004; Kotalik 2005). Resulting ethical guidance (University of Toronto 2005; Thompson et al. 2006; CDC 2007, 2011) offered principles for a response while acknowledging the importance of procedural values including reasonable and evidence based decision-making, inclusivity, transparency, and accountability.

Pandemic influenza also renewed focus within public health ethics on resource allocation as questions arose concerning how best to allocate scarce vaccines, hospital beds, ventilators and everyday supplies. The US National Vaccine Advisory Committee and Advisory Committee on Immunization Practices recommended giving priority to those in greatest medical need (US Department of Health and Human Services 2005), some asserted priority be given to those in whom we have invested some societal resources, yet who have not had opportunity to experience multiple life-stages, meaning young adults would be prioritized above infants (Emanuel and Wertheimer 2006), others underscored the importance of considering vulnerable populations in allocation (Uscher-Pines et al. 2007; Rosoff and DeCamp 2011; DeBruin et al.

2012), and some emphasized the importance of securing access for those with important roles in maintaining societal functioning and infrastructure (Kass 2001). Questions of resource allocation in a pandemic prompted procedural interests in public engagement as a strategy to incorporate public input into policy decisions (Bailey et al. 2011; Vawter et al. 2011).

Public health and social justice

Until recently, the more theoretical literature on justice and health focused almost exclusively on issues of access to healthcare and the allocation of scarce healthcare resources. While these remain important and contested areas of inquiry, the epidemiological evidence indicates that healthcare plays a relatively limited role in determining health status (Wilkinson and Marmot 2003). It has long been understood in public health that socioeconomic status (SES) (viz. status as defined by income, education, and occupation) is a major determinant of health, giving rise to significant health inequalities between social groups. Some health disparities are due to material conditions related to poverty, such as poor nutrition and crowded and unsanitary living conditions. But studies over the past two decades suggest that poverty alone does not explain the effects of SES on health. There is a gradient in life expectancy, mortality, and morbidity across all levels of the SES hierarchy (Marmot et al. 1991; Marmot and Shipley 1996). Health inequalities in the gradient that exist in the absence of material deprivations appear to be best explained by psychosocial factors, such as levels of social support and integration, control in the workplace, and hostility (Marmot 2004). There are also studies that, while controversial, suggest that an individual’s health is influenced by the level of income inequality in society as a whole, and not just by her own level of income (Kawachi et al. 1999). Increasing attention to the social determinants of health has given rise to a heightened focus on social justice in public health.

The central social justice issue in the context of public health concerns when health inequalities between social groups are unjust. There are several approaches in the literature to addressing this question, all of which are developed from more general theoretical accounts of distributive justice. Theories of distributive justice identify a metric specifying the good that is sought and a principle for the distribution of that good. The primary metrics include welfare, resources, and capabilities, while the competing principles of distribution appeal to equality, priority, and sufficiency.

Metrics of justice vary, with some viewing health as purely instrumental to the good justice seeks and others viewing health as intrinsic to that good. Instrumentalist accounts include Norman Daniels’ view that the value of health lies in its serving to secure equality of opportunity to pursue life plans (Daniels 1985, 2008) and the welfare egalitarian and contemporary utilitarian view that health is valuable insofar as it fulfils individual preferences. Each account is subject to the objection that health has value even when failing to promote these ends. Health seems important even for those near the end of life who have completed their life plans (Brock 1989; Segall 2010); health further can have value where one has a weak preference for it, particularly where the preference is due to an adaptation to conditions under which one has been persistently deprived of health (Sen 2009).

An alternative to the instrumentalist perspective conceives of health as partly constitutive of the ends of justice. Various capabilities theorists have argued that a person's ability to achieve good health is a fundamental capability inasmuch as health is essential to human life and flourishing (Sen 2002; Nussbaum 2006; Ruger 2009; Venkatapuram 2011). Madison Powers and Ruth Faden offer a related but distinct conception, viewing health as one of several dimensions of well-being (which also include personal security, respect, attachment, self-determination, and reasoning) that justice aims to secure. But they privilege the achievement of positive health outcomes over capabilities to achieve health, both because some individuals (children, in particular) are not well positioned to make free and informed choices about their health and because there are threats to health that may not be within an individual's ability to control (e.g., exposure to environmental harms) (Powers and Faden 2006, 2011).

In assessing whether a given health disparity is unjust, one must turn to distributive principles. On a strict egalitarian account, everyone should, as far as possible, have equal health status. This account has been widely dismissed as it would permit 'levelling down' the health status of some without improving the health of others as a means to achieve equality (Parfit 1998). Alternatively, the prioritarian account permits inequalities where they benefit those who are worst off. John Rawls' Difference Principle, which allows inequalities in income and wealth (among other goods) only where they benefit the worst off, is a prominent example of prioritarianism (Rawls 1971). Daniels has applied this view to health, suggesting that distributing social goods in accordance with the Difference Principle would substantially reduce the steepness of the health gradient (2008). Another prioritarian account gives weight to personal responsibility for health differentials, positing that those who do more to promote their health should be given priority (Segall 2010). Sufficientarians, like prioritarians, are concerned with how persons fare in absolute terms; but they hold that justice should ensure that everyone has enough of the goods essential to living a decent life, without regard to inequalities beyond the sufficiency threshold (Frankfurt 1987). Powers and Faden, for example, maintain that justice demands that everyone have a sufficient amount of health, and that the most pressing health inequalities are those that are systematically accompanied by inadequately met needs in other core dimensions of well-being (Powers and Faden 2006).

Given how many people lack adequate health and how little of the vast social and economic gains to the well-off have been accompanied by gains to the worst-off, following either the prioritarian or sufficientarian views of justice likely would lead to profound improvements in population health. While public health practitioners do not bear primary responsibility for addressing the full range of the social determinants of health, some argue that public health should more explicitly incorporate a social justice orientation. Strategies to do so are of course more challenging, and include monitoring social indicators related to health inequalities to engaging in community organization and collaborative practices that help promote the structural changes necessary to address the material and psychosocial causes of health disparities (Plough 2005).

Public health research

Literature in ethics and public health research falls into two categories. First, there is literature exploring how public health

research can be distinguished, conceptually and operationally, from public health practice (CDC 1999; Casarett et al. 2000; Bellin and Dubler 2001; Amoroso and Middaugh 2003). This literature outlines criteria for when an activity is quality assurance, surveillance, or evaluation versus when it is research requiring regulatory oversight (US Department of Health and Human Services 2009). This growing body of literature recognizes the blurry lines between research and practice in many arenas, including public health, and increasingly questions whether distinguishing research from practice is the most salient approach for ensuring ethical protection (Faden et al. 2013). As more data are available electronically, and with greater emphasis on learning healthcare systems and evidence-based practice (Institute of Medicine 2007; Kass et al. 2013), blurriness between research and practice will only grow larger.

Second, there is literature examining activities that unquestionably are research, but exploring whether public health research is different from clinical research, such that it should be exempt from certain regulatory requirements; literature also has addressed whether ethical challenges differ when entire populations are targeted for research.

Distinguishing public health research from non-research activities of public health

In 1999, the Centers for Disease Control and Prevention (CDC) issued what has become a widely cited document aimed at distinguishing public health research from non-research (CDC 1999). These guidelines were written in response to queries from outsiders whether certain data gathering activities conducted by CDC or by state health departments for public health practice should be categorized as research (Burris et al. 2003). While the guidelines were written to guide CDC employees in their own work, they have been used more broadly. The document asserts that public health practice can be distinguished from research based on what the primary intent of the activity is. If an activity is designed, primarily, to help a public health department do its job furthering the health interests of a particular community, even if it *also* produces data of more generalizable interest, the activity should be called non-research. Research, the guidance continued, is intended to produce generalizable knowledge, to have relevance beyond the population or programme from which data were collected. Surveillance, then, would be considered non-research when conducted in response to 'lawful state disease reporting or monitoring' activities. In 2001, the National Bioethics Advisory Commission echoed CDC guidance stating that projects *intended* to produce generalizable knowledge must be subject to the oversight provided by the Common Rule (National Bioethics Advisory Commission 2001).

The scholarly literature has echoed many of these concepts, especially that intention to produce generalizable knowledge characterizes research requiring federal oversight. Casarett et al. (2000), by contrast, suggest that activities should be regulated as research if: (1) the majority of patients involved are not expected to benefit directly from the knowledge to be gained and (2) additional risks and burdens exist as a result of wanting findings to be generalizable. Participants in a CDC workshop on practice versus

research recommended research oversight to be determined by level of risk, rather than distinguishing based on primary intent (MacQueen and Buehler 2004). Bellin and Dubler suggested activities can be considered non-research if there is a commitment to modify programs based on collected data (Bellin and Dubler 2001), and a recent framework suggests that the degree to which learning and collecting data increase risks or threaten important interests or well-being should dictate the degree of ethical oversight required, regardless of whether an activity is called research or practice (Faden et al. 2013).

Burris et al. contend that collection of data by government agencies fulfils their mandated functions and should be exempt from federal research regulations specifically because they are conducted by public health departments. They suggest an alternative, internal oversight system be created to ensure that ‘human beings who become involved in activities that increase our knowledge (whether defined as research or not) should be protected’ and ensure that data collection activities are conducted in the least harmful, least restrictive, and most respectful way possible (Burris et al. 2003).

Fairchild and Bayer, however, suggest *all* data collection by federal or state governments should be subject to ethical review. While not suggesting institutional review boards (IRBs) necessarily perform this review, they advocate for universal review of these activities (Fairchild and Bayer 2004). With so much non-health data widely used and shared through social media, and through the Internet more broadly, questions are emerging going forwards about whether views about health privacy will change as the sharing of health data likely also becomes more widespread (Voyena et al. 2012).

Ethical issues raised by public health research

Other literature explores whether ethics issues in *public health research* differ from those of clinical research. Papers from the 1970s and 1980s suggested that certain types of epidemiological studies using identifiable records should be exempt from informed consent requirements (Gordis et al. 1977; Kelsey 1981; Waters 1985). Gordis et al. provide dozens of examples, from identifying the link between cigarette smoking and lung cancer, to the link between high concentrations of oxygen for premature infants and blindness, to the link between oral contraceptives and stroke, illustrating the contributions that epidemiological record review has made to public health and suggesting such methods would be nearly impossible if consent were required (Gordis et al. 1977). More recent literature examines whether and how population-based or prevention research differs in ethically relevant ways from clinical research (Taylor and Johnson 2007). Population-based research may not allow individual participants the opportunity to refuse participation, for example, when studies investigate community-wide interventions, like the impact of health promotion media campaigns in some communities and not others. In such cases, IRBs must confirm that risk to individuals is minimal and public health benefit from the research outweighs concerns imposed by individuals’ inability to refuse. Data are generally collected at the population level without individual identifiers.

Population-based research has the potential to stigmatize identifiable groups if the research targets specific geographic, religious,

or ethnic communities, or groups defined by a risk behaviour such as injection drug use or sexual orientation. The potential for stigma and social harms was a prominent concern of genetic research and the launch of the Human Genome Diversity Project in 1991, as entire races and indigenous communities were the unit of interest. Social harms animated a recent case, *Havasupai Tribe v. Arizona Board of Regents*. Stored genetic samples for research ultimately undermined traditional understandings of the tribe’s ancestral origin, indicated high levels of inbreeding within the tribal community, and assessed associations with schizophrenia, a highly stigmatized condition within the tribe (*Havasupai Tribe v. Arizona Board of Regents* 2008). While research ethics has traditionally allowed analysis of samples that are not individually identifiable, this case demonstrated that population-based research carries the risk that outsiders might think differently about an entire social group as a result of research findings.

It is then not surprising that population-based research is the origin of both community advisory boards (Strauss et al. 2001; Morin et al. 2003; Quinn 2004) and community-based participatory methods (Israel et al. 1998; Macaulay et al. 1999), strategies designed to include community input into planned research methods and dissemination plans. Challenges remain regarding what is meant by ‘community’ and ‘engagement’ in the context of research (Hillery 1955; CDC 1997; MacQueen et al. 2001; Sharp and Foster 2007), as well as determining when community input must be sought, when a community has been fully represented, and how to resolve disputes within communities (Sharp and Foster 2007).

Research in resource-poor settings raises additional ethical challenges, both globally and domestically, and points to why the CIOMS guidelines include sections that other research ethics guidelines do not on incentives, responsibilities when studies are over, and justice. A major controversy erupted in 1997 after US-funded HIV trials in low-income countries tested the efficacy of drugs to prevent vertical transmission of HIV. Studies were placebo-controlled even when an effective, albeit expensive and complex, treatment protocol existed. While some scholars and human rights activists asserted that use of placebo was in clear violation of ethical guidelines, causing millions of infants to contract HIV (see Lurie and Wolfe 1997), others argued that women in the trials were no worse off by participating in trials, and placebo-controlled designs more validly tested whether locally relevant interventions were effective, to then be implemented in the field more quickly (Varmus and Satcher 1997). The controversy resulted in multiple revisions of the Declaration of Helsinki and CIOMS guidelines on the use of placebos, yet consensus on this question has not been reached.

Finally, similar to clinical trials, population-based trials—particularly those conducted in resource-poor settings—increasingly must consider what, if anything, will be made available to study communities when the research is completed. Several national and international bodies have suggested that successful research interventions should be made reasonably available to host country communities (CIOMS 2002; National Bioethics Advisory Commission 2001)—or at least justify why such availability is impossible if that is the case (Nuffield Council of Bioethics 2002), while others argued that many donor or government commitments never could have been secured until study results were in hand. An alternative approach suggested that ‘fair benefits’

should be provided to communities, regardless of whether those benefits are directly related to the study intervention being tested (Conference on Ethical Aspects of Research in Developing Countries 2004). Recent HIV Prevention Trial Network (HPTN) ethics guidance acknowledges that although conclusive definitions of post-study access agreements may not be possible prior to testing the intervention, the development of a detailed, preliminary plan of post-study access is nonetheless necessary (HPTN 2009).

Important in the evolution of thinking about public health research ethics was a controversial legal case of 2001 related to a lead abatement trial conducted in the 1990s in Baltimore (*Ericka Grimes v. Kennedy Krieger Institute, Inc.* 2001). This trial targeted low-income housing units in old neighbourhoods that had significant lead paint in units and where units often were in disrepair; that is, where children would be at risk of lead poisoning due to the existing poor conditions (Farfel and Chisolm 1990, 1991, 1994; Pollak 2002). Despite evidence existing for decades documenting the danger of lead paint to children, no laws existed requiring that houses be safe or abated before they could be rented to families. In the trial, households were randomized to one of several different lead abatement strategies to see the effect on both household lead dust and children's own blood lead levels of the different abatement strategies. Two families later brought lawsuits, charging that researchers failed to warn them in a timely manner that children might still be at risk of lead poisoning. This case was paradigmatic of certain types of public health research, in that it targeted a particular community, it dealt with prevention of a major public health problem, and, significantly, it was designed to respond to a series of baseline conditions that were harmful to public health. There remains no consensus regarding whether research is exploitive when situated in settings of neglect and when testing interventions that may improve conditions, but will not improve them as much as other, existing, but clearly unavailable interventions. Scholars have questioned whether conducting research on 'partial solutions' condones the idea that partial solutions are adequate for the disadvantaged (Farmer and Campos 2004; Spriggs 2004; Buchanan and Miller 2006; Kass 2008). Miller and Buchanan suggest that rejecting all research on partial solutions out of a 'presumption that a particular conception of justice will eventually prevail'—sacrifices the welfare of 'literally millions' of (in this case) children who could benefit from the results of the partial solutions tested through public health prevention research. Related, they assert that it is inappropriate to blame researchers for 'the lack of social consensus' on the right to better social conditions and that doing so is 'misplaced indignation' (Buchanan and Miller 2006). Others, however, suggest that even the perception of exploitation raised through this case is harmful for the research enterprise and suggests a need for 'true partnership in the research enterprise, particularly when proposed research involves vulnerable communities' (Mastroianni and Kahn 2002).

Ethical issues raised by genetic research

The rapid advancement of genetic research over the past two decades has presented new challenges for public health research, including issues of consent for storage of genetic material, return

of genetic test results, and assignment of ownership of genetic material.

Because biospecimens used in genetic research are frequently collected and stored in a 'biobank' from which they are accessed for a wide range of future studies, it is not always possible to know how specimens may be used in the future. Re-contacting participants each time their sample will be used has been viewed as impractical and overly burdensome to both researchers and participants, yet 'blanket consent,' in which participants agree to any future use of their samples, has been criticized as an insufficient means of respecting participant autonomy (McGuire and Beskow 2010). While empirical work shows most participants support data-sharing initiatives that enable widespread use of their samples, participants expressed lingering concerns about the capacity of data-sharing initiatives to fully protect participant data, suggesting initiatives should be transparent to maintain trust with participant populations (Trinidad et al. 2010). At the same time, there is increasing opportunity for individuals to upload their own genetic data into private non-profit and commercial databases for use by a wide network of researchers, for example, through online initiatives such as 'Consent to Research' (<http://weconsent.us/>) and the 'Personal Genome Project' (www.personalgenomes.org). As biobanks have sprung up across the globe and information is increasingly available electronically, the potential for global data sharing is quickly becoming a reality (Kaye 2011). While such interconnectedness leverages the resources available to researchers and opens new opportunities for research, it amplifies the potential for uncontrolled use of specimens well beyond original and anticipated uses. Consent procedures for biobanking and the ethics of global data sharing is in its infancy, and ethicists are grappling with the challenges of developing controls and accountability mechanisms (Gottweiss and Lauss 2010; O'Doherty et al. 2011).

Disclosure of results from genetic tests performed during research also raises controversy. Some argue results should be returned as a way to respect autonomy and allow participants to find meaning in results even without clinical implications; returning results may also demonstrate reciprocity for having participated in research (Ravitsky and Wilfond 2006). Others counter that supplying genetic results that are often complex and offer limited clinical value would be misleading and potentially harmful (Beskow 2006). Even when results are readily interpretable and have clinical implications, informing participants of results requires retaining linkages to individual samples. The National Bioethics Advisory Commission and the National Cancer Institute's Best Practices for Biospecimen Resources state merely that the informed consent document contain a statement explaining whether, which, and to whom individual results would be released (National Bioethics Advisory Commission 1999; National Cancer Institute 2011). Taking a stronger stance, the National Heart, Lung and Blood Institute convened working groups in 2004 and 2009 that drafted recommendations outlining conditions under which results ethically should be returned, circumstances in which research may but should not be expected to return results, and that emphasized the importance of community engagement when working with identifiable communities (Fabsitz et al. 2010).

Finally, genetic research has given rise to questions of identity, ownership, and property in ways not seen in other types

of public health research. Law suits filed in the early 1990s and 2000s addressed ownership of biological material used in genetic research (*Moore v. Regents of the University of California* 1990; *Greenberg v. Miami Children's Hospital Research Institute* 2003; *Washington University v. Catalona* 2007) and plaintiffs claimed a property right to the materials developed from their genetic samples. Defendants argued that samples were 'donated' and individuals relinquished ownership rights when samples were collected. Case law to date has favoured the research enterprise in rulings that do not recognize participant ownership of biospecimens collected for research, yet questions remain, ethically, as to whether viewing biospecimens as property is appropriate. McGuire and Beskow outline numerous approaches to informed consent in genetic research, (McGuire and Beskow 2010), and the National Human Genome Research Institute maintains a comprehensive web resource for conducting informed consent in genetic research. In addition, new initiatives seek to address these challenges through participant engagement (Kaye et al. 2012). Finally, emerging participatory models propose the use of social media as a way to form relationships between participants and researchers. As a means of ongoing communication, these initiatives empower participants to make informed choices over the use of their samples and provide a mechanism to communicate findings as their interpretation changes over time.

Conclusion

Public health has been given significant attention in the bioethics literature only in the last three decades. Public health must balance furthering the health of communities through education, surveillance, interventions, and regulations with needing to restrict the freedoms or privacy of individuals affected to the minimum degree possible while also addressing core commitments to social justice. Public health is granted statutory authority to protect the public's health and, indeed extraordinary public health improvement has been achieved through sanitary measures, restaurant inspections, immunizations, and health education. At the same time, it is expressly because of this authority that ethics has such a critical role to play. Clear frameworks of ethics that outline a need for data, minimizing of harms, fair procedures, and clear principles to follow, including transparency, reciprocity, and equity, can help public health fulfil its duty to improve health on behalf of all of us, while allowing individuals to feel confident that any restrictions are appropriate and fairly defined. Public health research requires some new considerations for research ethics including the need to be more cognizant of the implications of research for populations as a whole, for finding creative ways to seek community-wide input, and to begin to consider how to ensure that communities, as well as individuals, realize research benefit.

Notes

1. Note that the 11th edition of the same textbook (1980) had a chapter entitled 'Legal and Ethical Issues in Public Health' by Sidney Shindell. The bulk of this chapter is devoted to legal issues in public health, however, rather than ethics issues, and thus is not discussed here.
2. Note that this article describes the work of Edward Chadwick in England in the early 1800s demonstrating that differences in social conditions led to a more than twofold difference in life expectancy between upper and lower classes. Also in the 1800s, governments began conducting

investigations of housing conditions and garbage heaps and mapping them in relation to outbreaks of disease, and by the end of the nineteenth century, state and local boards of health were being created to enforce sanitary regulations.

Human rights

What are human rights?

Human rights are freedoms and entitlements concerned with the protection of the inherent well-being, dignity, and equality of every human being. They include civil, political, economic, social, and cultural rights. The international community has accepted the position that all human rights are universal, indivisible, interdependent, and interrelated (United Nations (UN) 1993).

Although inspired by moral values, such as dignity and equality, human rights are more than moral entitlements: They are legally guaranteed through national and international legal obligations on duty bearers. They are enshrined, for example, in various international treaties and declarations.

International human rights treaties (often called covenants or conventions), such as the International Covenant on Economic, Social and Cultural Rights (ICESCR), are legally binding on the States that ratify them ('States parties'). In contrast, human rights declarations, such as the Universal Declaration of Human Rights, are non-binding, although many of them do include norms and principles that reflect obligations that are binding under customary international law.

Human rights have traditionally been concerned with the relationship between the State, on one hand, and individuals and groups on the other. By ratifying international human rights treaties, States assume binding legal obligations to give effect to the human rights enumerated within them.

Additionally, all States have national laws that protect some human rights. Moreover, some States have enshrined human rights—civil, political, economic, social, and cultural—in their constitutions.

Historic neglect of economic, social, and cultural rights, such as the rights to health and shelter, is gradually being overcome, thanks in part to civil society organizations across the world that have campaigned for their equal representation and advocated for specific mechanisms for their enforcement.

Who has human rights duties?

Although only States are parties to international and regional human rights treaties, and are thus fully accountable for

compliance with their provisions, all members of society have responsibilities regarding the realization of human rights, including the right to the highest attainable standard of health (UN 1948, preamble; UNCESCR 2000, para. 42). This includes health workers, families, communities, inter- and non-governmental organizations, civil society groups, as well as the private business sector: these so-called 'non-State actors' all have responsibilities regarding the realization of the right to health. States, as parties to international treaties, have a duty to provide an environment in which all of these individuals and groups can discharge their human rights responsibilities.

Approaches to human rights

One approach to the vindication of human rights is via the courts, tribunals, and other judicial and quasi-judicial processes (the 'judicial' approach). Another approach, however, brings human rights to bear upon policymaking processes so that policies and programmes that promote and protect human rights are put in place (the 'policy' approach). Although the two approaches are intimately related and mutually reinforcing, the distinction between them is important because the 'policy' approach opens up challenging new interdisciplinary possibilities for the operationalization of human rights.

Lawyers have played an indispensable role in developing the norms and standards that today constitute international human rights law. Naturally, when it comes to the 'judicial' and 'policy' approaches, some lawyers are professionally drawn to the former. Indeed, in the context of the right to health, despite some suggestions to the contrary, this approach has a vital role to play and many courts have demonstrated that they have a crucial contribution to make (UNHRC, 2007; Gauri and Brinks 2008; Yamin and Gloppen 2011). It is important that this judicial contribution deepens and becomes more widespread.

In addition to this approach, however, it is vital that the right to health is brought to bear upon all relevant local, national and international policymaking processes. This 'policy' approach depends upon techniques and tools—indicators, benchmarks, impact assessments, and so on—that demand close cooperation across a range of disciplines. Given its historic role and traditional expertise, public health has an indispensable contribution

to make to the ‘policy’ approach. The later section ‘New tools and techniques’ briefly introduces some of these techniques and tools in the specific context of the right to the highest attainable standard of health.

What is the right to health?

Sources of the right to health

The origins of the international right to the highest attainable standard of health can be traced back over 60 years. Adopted in 1946, the World Health Organization’s (WHO) Constitution states: ‘The enjoyment of the highest attainable standard of health is one of the fundamental rights of every human being without distinction of race, religion, political belief, economic or social condition’. Two years later, article 25(1) of the Universal Declaration of Human Rights laid the foundations for the international legal framework for the right to health. Since then, the right to health has been codified in numerous legally binding international and regional human rights treaties, and enshrined in many national laws, some of which are signalled in the following paragraphs. This gives rise to one of the most important and distinctive characteristics of human rights, including the right to the highest attainable standard of health. Human rights place legally binding obligations on States.

International human rights law

Concrete legal duties are conferred upon States when they ratify international treaties; they must ensure that all individuals within their jurisdiction can enjoy the rights envisaged within them. The cornerstone protection of the right to health in international law is found in Article 12 of ICESCR. Over 155 States have legally bound themselves, through ratification of this treaty, to its implementation.

Additional right to health protections are contained in international treaties that address issues specific to marginalized groups, such as the International Convention for the Elimination of All Forms of Racial Discrimination (CERD, Article 5(e)(iv)); the International Convention on the Elimination of All Forms of Discrimination Against Women (CEDAW, Articles 11(1)f, 12, and 14(2)b); the Convention on the Rights of the Child (CRC, Articles 3(3), 17, 23, 24, 25, 28, and 32); and the Convention on the Rights of Persons with Disabilities (CRPD, Articles 25 and 26).

Authoritative and interpretive guiding principles of several of these treaty provisions on the right to health—called General Comments or General Recommendations—shed further light on the parameters and content of the right to health generally, and in relation to the application of the right to specific groups. In 2000, for example, the UN treaty-body responsible for monitoring ICESCR adopted General Comment 14 on the right to the highest attainable standard of health.

Moreover, some UN treaty-bodies have decided cases that shed light on the scope of health-related rights. Recently, for example, the Human Rights Committee considered the case of a 17-year-old Peruvian who was denied a therapeutic abortion. When K.L. was 14 weeks pregnant, doctors at a public hospital in Lima diagnosed the fetus with an abnormality that would endanger K.L.’s health if pregnancy continued. However, K.L. was denied a therapeutic abortion by the hospital’s director. In *K.L. v. Peru*, the Human Rights Committee decided that by denying the young woman’s

request to undergo an abortion in accordance with Peruvian law, the Government was in breach of its right-to-life obligations under the International Covenant on Civil and Political Rights (UNHRCtee 2003).

Further standards relating to specific groups are set out in non-binding legal instruments, such as the Declaration on the Elimination of Violence against Women. Additional international human rights instruments contain protections relevant to the right to health in various situations, environments and processes, including armed conflict, development, the workplace, and detention (UNCHR 2003a, Annex I).

Significantly, resolutions of the UN Commission on Human Rights, including those on disabilities and access to medication (UNCHR 2002a, 2002b), have articulated the right to the highest attainable standard of health; while other important resolutions contain provisions that bear closely upon the right (UNCHR 2003a, Annex II).

Far-reaching commitments relating to the right to health have been made in the outcome documents of numerous UN world conferences, such as the International Conference on Population and Development (UN 1994), the Fourth World Conference on Women (UN 1995), and the Millennium Declaration (UNGA 2000). These conferences have helped to place international problems, including health issues such as HIV/AIDS, at the top of the global agenda and their outcome documents influence international and national policymaking. Several refer to the right to health and health-related rights.

Regional human rights law

The right to health is recognized in human rights treaties drafted and monitored by the different regional human rights systems. These have effect only in their respective regions and include: the African Charter on Human and Peoples’ Rights (Article 16); the African Charter on the Rights and Welfare of the Child (Article 14); the Additional Protocol to the American Convention on Human Rights in the Area of Economic, Social and Cultural Rights, known as the ‘Protocol of San Salvador’ (Article 10); and the European Social Charter (Article 11). Other regional instruments, such as the American Convention on Human Rights (OAS 1969) and European Convention for the Protection of Human Rights and Fundamental Freedoms (Council of Europe 1950), provide, through health-related rights, indirect protection of the right to health.

At regional level there are also judicial and other mechanisms that adjudicate cases involving the right to health. A notable case in 2002 was the finding by the African Commission on Human and Peoples’ Rights of a violation of the right to health by the Federal Republic of Nigeria, on account of violations against the Ogoni people in relation to the activities of oil companies in the Niger Delta (ACHPR 2001).

Significantly, regional mechanisms have also found breaches of other health-related rights, including the violation of the right to a home and family and private life, arising from environmental harm to human health in *López Ostra v. Spain* (ECtHR 1994), as well as the negative consequences on children’s health stemming from the occurrence of child labour in *ICJ v. Portugal* (ECSR 1998).

Another important development has come from the Inter-American Commission on Human Rights, which expressed its willingness to ‘take into account’ provisions of the regional

treaty (the Protocol of San Salvador) related to the right to health when analysing the merits of a case, even though it lacked competence to determine violations under them (IACHR 2000).

National law

A study has shown that 67.5 per cent of the constitutions of all nations have provisions regarding health and healthcare (Kinney and Clark 2004). In addition, a large number of constitutions set out States' duties in relation to health, such as the duty to develop health services, from which it is possible to infer health entitlements.

In some jurisdictions these constitutional provisions have generated significant jurisprudence, such as the decision of the Constitutional Court of South Africa in *Minister for Health v. Treatment Action Campaign*. In this case, the Court held that the Constitution required the Government 'to devise and implement a comprehensive and coordinated programme to realize progressively the right of pregnant women and their newborn children to have access to health services to combat mother-to-child transmission of HIV' (CCSA 2002, para. 135 (2) (a)). This case—and numerous other laws and decisions at the international, regional, and national levels—confirms that the courts have an important role to play in the protection of the right to the highest attainable standard of health.

Right to health in the context of other human rights

As already indicated, the right to health is closely related to and dependent upon the realization of other fundamental human rights contained within international law. These include the rights to life, food, housing, work, and education, as well as rights based on the freedom not to be tortured or discriminated against. Similarly, the rights to privacy, equality, access to information, and freedom of association, as well as other rights and freedoms, relate to and address integral components of the right to health.

The right to health—like other economic, social, and cultural rights—does not escape controversy and ideological objections. Some States are still reluctant to see it as a right of similar weight to others, such as the right to a fair trial. However, under international law, the right to the highest attainable standard of health is an integral part of the international code of human rights and must be given equal treatment and attention. Importantly, the interdependence and equal footing of all human rights was reaffirmed in the Vienna Declaration (UN 1993, para. 5). Furthermore, jurisprudence and international standards are gradually clarifying the mutually reinforcing relationship between the right to health and other health-related rights, such as the right to life (UNCESCR 2000, para. 3).

The complementary relationship between public health and the right to health

With a few exceptions, the relationship between health and human rights was not subject to close examination until the 1990s. Of course, the Constitution of WHO (WHO 1946) affirms the right to health and so does the Declaration of Alma Ata (WHO 1978a). Also, some of those who were struggling against HIV/AIDS in the 1980s recognized the crucial importance of human rights.

But, for the most part, these important developments were not accompanied by a detailed examination of the substantive relationship between health and human rights. That had to wait until the early 1990s. A great debt is owed to the late Jonathan Mann and his colleagues at the Harvard School of Public Health and the Francois-Xavier Bagnoud Center for Health and Human Rights for their pioneering work on the relationship between health and human rights, especially in the context of HIV/AIDS (Grodin et al. 2013).

In the 1990s, however, Dr Mann and others suffered from a serious limitation that does not apply today. At that time, although there was a widespread and detailed understanding of many human rights, there was no comparable understanding of the right to the highest attainable standard of health, even though this human right is the cornerstone of the relationship between health and human rights.

Today, however, the situation is significantly different. In 2000, an authoritative understanding of the right to health emerged when the UN Committee on Economic, Social and Cultural Rights, working in close collaboration with WHO and many others, adopted General Comment 14 (UNCESCR 2000). Also, some international bodies like WHO, UNFPA, UNICEF, and UNAIDS, as well as civil society organizations, have begun to give more careful attention to health-related rights, including the right to the highest attainable standard of health. These and other developments have deepened understanding of the right to health, enabling linkages to be made between public health and human rights, a process that continues to accelerate through good practice, the academic literature and widening jurisprudence.

Although in some quarters there is a presumption that the right to health relates to medical care, such a narrow definition is in fact inconsistent with international human rights law, which encompasses both medicine and public health, as confirmed by Article 12 of ICESCR and Article 24 of CRC. As well as access to medical care, the right to health encompasses the social, cultural, economic, political, and other conditions that make people need medical care in the first place (WHO 1946, preamble; Beaglehole 2002), as well as other determinants of health such as access to water, sanitation, nutrition, housing, and education. This wider perspective underscores the very extensive common ground between public health and the right to the highest attainable standard of health.

The right to the highest attainable standard of health depends upon public health measures, such as immunization programmes, the provision of adequate sanitation systems and clean drinking water, health promotion (e.g. regarding domestic violence, healthy eating, and taking exercise), road safety campaigns, nutrition programmes, the promotion of indoor stoves that reduce respiratory diseases, and so on. Also, however, the classic, long-established public health objectives can benefit from the newer, dynamic discipline of human rights. In other words, just as public health programmes are essential to the realization of the right to health, so too can human rights help to reinforce existing, good, health programmes and identify new, equitable, health policies. This chapter focuses on the relevance of the right to the highest attainable standard of health to public health. However, the indispensable contribution of public health to the right to the highest attainable standard of health also deserves careful study.

Both public health and human rights advocates wish to establish effective, integrated, responsive health systems that are accessible to all. Both stress the importance not only of access to healthcare, but also to water, sanitation, health information, and education. Both understand that good health is not the sole responsibility of the Ministry of Health, but belongs to a wide range of public and private actors. Both prioritize the struggle against discrimination and disadvantage, and both stress cultural respect. At root, those working in health and human rights are both animated by a similar concern: the well-being of individuals and populations.

Health workers—defined in the World Health Report of 2006 (WHO 2006a) as ‘all people engaged in actions whose primary intent is to enhance health’—can use health-related rights to help them devise more equitable policies and programmes; to place important health issues higher up national and international agendas; to secure better coordination across health-related sectors, as well as between services within the health sector; to raise more funds from the treasury; to leverage more funds from developed countries to developing countries; in some countries, to improve the terms and conditions of those working in the health sector; and so on. The right to the highest attainable standard of health is not just a rhetorical device, but also a tool that can save lives and reduce suffering, especially among the most disadvantaged.

The following sections provide examples that illustrate the resonance between public health and the right to the highest attainable standard of health.

Although these two disciplines are, in many ways, complementary, in practice public health has been used by some States as a ground for limiting the exercise of some human rights. Indeed, under international law, States are allowed to impose some limitations on human rights, in some circumstances, for the protection of public health, an issue briefly revisited in the following section.

The contours and content of the right to health

The right to health is not a right to be healthy. It is a right to facilities, goods, services, and conditions that are conducive to the realization of the highest attainable standard of physical and mental health. Understanding of the content of the right has evolved considerably over the last 60 years, with jurisprudence, international standards, and practical implementation of the right all contributing to this process.

As we have seen, an inclusive approach to implementing the right to the highest attainable standard of health calls for its reach to extend not only to timely and appropriate medical care, but also to the underlying determinants of health, such as access to safe and potable water and adequate sanitation, healthy occupational and environmental conditions, and access to health-related education and information (UNCESCR 2000, para. 8).

The right to health can also be broken down into more specific entitlements, such as the rights to: maternal, child, and reproductive health; healthy workplace and natural environments; the prevention, treatment, and control of diseases, including access to essential medicines; and access to safe and potable water.

In times of emergency, States have a joint and individual responsibility to cooperate in providing disaster relief and humanitarian assistance, including medical aid and potable water

as well as assistance to refugees and internally displaced persons (UNCESCR 2000, para. 40).

Certain limitations on the right to health do exist, as issues of public health are sometimes used by States as grounds for limiting the exercise of other fundamental rights. For such limitations to be implemented legitimately, they must be in accordance with the law and international human rights standards. In particular, they should be strictly necessary for the promotion of the general welfare in a democratic society, proportional, subject to review, and of limited duration (UN ECOSOC 1985, Annex; UNCESCR 2000, paras. 28–9).

The right to health analytical framework

In recent years, the Committee on Economic, Social and Cultural Rights, WHO, the first Special Rapporteur on the right of everyone to the enjoyment of the highest attainable standard of physical and mental health, civil society organizations, academics, and many others, have developed a way of ‘unpacking’ or analysing the right to health with a view to making it easier to understand and apply to health-related policies, programmes, and projects in practice. The analytical framework that has been developed is made up of ten key elements and has general application to all aspects of the right to health, including the underlying determinants of health: this has been demonstrated by the first Special Rapporteur in his use of the framework throughout his work (Hunt and Leader 2010).

National and international human rights laws, norms, and standards

The relevant laws, norms, and standards relevant to the particular issue, programme, or policy must be identified. These will include both general provisions and standards relating to the right to health, in addition to international instruments that relate to specific groups and contexts (see the section ‘What is the right to health?’) (UNCHR 2003a, Annex 1).

Resource constraints and progressive realization

International human rights law recognizes that the realization of the right to health is subject to resource availability. Thus, what is required of a developed State today is of a higher standard than what is required of a developing State. However, a State is obliged—whatever its resource constraints and level of economic development—to realize progressively the right to the highest attainable standard of health (UN 1966b, Art. 2(1)). In essence, this means that a State is required to be doing better in 2 years’ time than it is doing today. In order to measure progress (or the lack of it) over time, indicators and benchmarks must be identified (see the section ‘New tools and techniques’).

Obligations of immediate effect

Despite resource constraints and progressive realization, the right to health also gives rise to some obligations of immediate effect, such as the duty to avoid discrimination (UNCESCR 2000, para. 43). These are obligations without which the right would be deprived of its *raison d’être* and as such they are not subject to progressive realization, even in the presence of resource constraints (UNCESCR 1990, para. 10). The precise scope of these immediate obligations has not yet been clearly defined; for the health and human rights communities, this remains important work-in-progress.

Freedoms and entitlements

The right to health includes both freedoms (for example, the freedom from discrimination or non-consensual medical treatment and experimentation) and entitlements (for example, the provision of a system of health protection that includes minimum essential levels of water and sanitation). For the most part, freedoms do not have budgetary implications, while entitlements do.

Available, accessible, acceptable, and good quality

All health services, goods, and facilities should comply with each of these four requirements. An essential medicine, for example, should be *available* within the country. Additionally, the medicine should be *accessible*. Accessibility has four dimensions: accessible without discrimination, physically accessible, economically accessible (i.e. affordable), and accessible health-related information. As well as being available and accessible, health services should be provided in a culturally *acceptable* manner. This requires, for example, effective coordination and referral with traditional health systems. Lastly, all health services, goods, and services should be of *good quality*; a medicine, for example, must not be beyond its expiry date. These four requirements are further explored and applied in the section ‘Right to health issues through the analytical framework’.

Note the similarity between these requirements and the four ‘As’ of public healthcare envisaged since the 1978 Alma Ata Declaration: geographical accessibility, financial accessibility, cultural accessibility, and functional accessibility (WHO 1978b).

Respect, protect, fulfil

This subsidiary framework relates to the tripartite obligations of States to respect, protect, and fulfil the right to the highest attainable standard of health, as explained and used by CESCR, the Committee on the Elimination of Discrimination Against Women (CEDAW) and the Sub-Commission on the Promotion and Protection of Human Rights. A version of this subsidiary framework is also enshrined in the Constitution of South Africa.

For example, the obligation to *respect* places a duty on States to refrain from interfering directly or indirectly with the enjoyment of the right to health. The obligation to *protect* means that States must prevent third parties from interfering with the enjoyment of the right to health. The obligation to *fulfil* requires States to adopt necessary measures, including legislative, administrative and budgetary measures, to ensure the full realization of human rights, including the right to the highest attainable standard of health.

Non-discrimination, equality, and vulnerability

Because of their crucial importance, the analytical framework demands that special attention be given to issues of non-discrimination, equality, and vulnerability in relation to all elements of the right to the highest attainable standard of health.

Active and informed participation

Participation is grounded in internationally recognized human rights, such as the rights to participate in the formulation and implementation of government policy (CEDAW, Article 7(b)), to take part in the conduct of public affairs (ICCPR, Article 25(a); UN 1966a), and to freedom of expression and association (ICCPR, Articles 19 and 22). The right to health requires that there be an opportunity for individuals and groups to participate actively and

in an informed manner in health policymaking processes that affect them (UNCESCR 2000, para. 54).

International assistance and cooperation

In line with obligations envisaged in the UN Charter and some human rights treaties, such as the ICESCR (Article 2) and the CRC (Article 4), developing countries have a responsibility to seek international assistance and cooperation, while developed States have some responsibilities towards the realization of the right to health in developing countries (Hunt et al. 2010; Maastricht Principles on Extraterritorial Obligations of States in the Area of Economic, Social and Cultural Rights 2011).

Monitoring and accountability

The right to health introduces globally legitimized norms or standards from which obligations or responsibilities arise. These obligations have to be monitored and those responsible held to account. Without monitoring and accountability, the norms and obligations are likely to become empty promises. Accountability mechanisms provide rights-holders (e.g. individuals and groups) with an opportunity to understand how duty-bearers have discharged their obligations, and it also provides duty-bearers (e.g. ministers and officials) with an opportunity to explain their conduct. In this way, accountability mechanisms help to identify when—and what—policy adjustments are necessary. Accountability tends to encourage the most effective use of limited resources, as well as a shared responsibility among all parties. Transparent, effective, and accessible accountability mechanisms are among the most crucial characteristics of the right to the highest attainable standard of health.

These ten key elements of the right-to-health analytical framework underscore what the right to health contributes to public health. For example, the preoccupation with non-discrimination, equality, and vulnerability requires a State to take effective measures to address the health inequities that characterize some populations. The focus on active and informed participation requires a State to adopt, so far as possible, a ‘bottom-up’ participatory approach in health-related sectors. The requirement of monitoring and accountability can help to ensure that health policies, programmes, and practices are meaningful to those living in poverty.

Crucially, the key elements of the right-to-health analytical framework are not merely to be followed because they accord with sound management, ethics, social justice, or humanitarianism. States are required to conform to the key features *as a matter of binding law*. Moreover, they are to be held to account for the discharge of their right-to-health responsibilities arising from these legal obligations.

Right to health issues through the analytical framework

In this section, elements of the analytical framework signalled in the section ‘The contours and content of the right to health’ are applied to a selection of health issues. While space does not permit all of the elements to be applied to all of the selected issues, each element is applied to at least one of them.

The selected health issues are: neglected diseases; mental disabilities; sexual and reproductive health, including maternal mortality; and water and sanitation. The right to health is among the most extensive and complex in the international lexicon of human

rights. As already signalled, it extends much further than these four issues which are simply provided as an illustration of how the right-to-health analytical framework applies to this selection of important health issues.

Neglected diseases

Although there is no standard global definition of 'neglected diseases', nor are they homogenous, they tend to share some common features. For example, they typically affect neglected populations, those least able to demand services. They are a symptom of poverty and disadvantage. Fear and stigma are attached to some neglected diseases, leading to delays in seeking treatment and to discrimination against those afflicted.

Neglected diseases include lymphatic filariasis, schistosomiasis, onchocerciasis (river blindness), trachoma, Buruli ulcer, soil-transmitted helminths, leishmaniasis, leprosy, and human African trypanosomiasis (sleeping sickness). According to WHO, 'the health impact of...neglected diseases is measured by severe and permanent disabilities and deformities in almost 1 billion people' (WHO 2002, p. 96).

Where curative interventions for neglected diseases exist, they have generally failed to reach populations early enough to prevent impairment. Furthermore, the development of new tools to diagnose and treat them has been underfunded, largely because there has been little or no market incentive (WHO 2004a, p. 22).

Non-discrimination, equality, and vulnerability

Discrimination and social stigma can be both causes and consequences of certain neglected diseases. As non-discrimination and equal treatment are cornerstone principles in international human rights law, a rights-based approach to neglected diseases pays particular attention to policies, programmes, and projects that impair the equal enjoyment of the human rights of people suffering from these diseases (WHO and TDR 2007).

Stigmatization and discrimination heighten people's vulnerability to ill health. Often, stigmatization is based on myths, misconceptions, and fears, including those related to certain diseases or health conditions. In turn, fear of stigmatization can lead people living with neglected diseases to avoid diagnosis, delay seeking treatment and hide the diseases from family, employers, and the community at large.

Discrimination involves acts or omissions which may be directed towards stigmatized individuals on account of their health status and/or related disabilities. For example, leprosy, lymphatic filariasis and leishmaniasis may cause severe physical disabilities, including deformities and scarring, giving rise to discrimination in the workplace, and limiting access to healthcare and education.

The socioeconomic consequences of stigmatization and discrimination associated with neglected diseases can have devastating consequences for individuals and groups that are already marginalized, leading to further vulnerability to neglected diseases. For example, stigma related to tuberculosis can be greater for women: it may lead to ostracism, rejection, and abandonment by family and friends, as well as loss of social and economic support and other problems (WHO 2001a, p. 12). Social and behavioural research on stigma and neglected diseases suggests that women also may experience more social disadvantages than men, in particular from physically disfiguring conditions like lymphatic filariasis (Coreil et al. 2003, p. 42).

The guarantee of non-discrimination and equal treatment enshrined under national and international human rights law requires the government to adopt wide-ranging measures, including through the implementation of health-related laws and policies, which confront discrimination in the public and private sector.

Active and informed participation

A human rights approach not only attaches importance to reducing the incidence and burden of neglected diseases, but also to the democratic and inclusive processes by which these objectives are achieved. Such processes require the active, informed, and meaningful participation of communities affected by neglected diseases.

Affected communities have sometimes participated in aspects of prevention, treatment, and control of neglected diseases. For example, they are sometimes involved in vector control programmes, such as bednet impregnation to combat malaria, or housing improvements to combat Chagas disease, which is caused by parasites living in cracks in housing. Communities have also been involved in treatment strategies, for example, through community health workers who have been selected and trained to administer vaccinations and treatment (Espino et al. 2004).

However, the human rights approach means that affected communities should participate in a range of contexts, not just in implementing programmes. They should be actively involved in setting local, national, and international public health agendas; decision-making processes; identifying disease control strategies and other relevant policies; and holding duty bearers to account. While it is not suggested that affected communities should participate in all the technical deliberations that underlie policy formulation, their participation can help to avoid some of the top-down, technocratic tendencies often associated with old-style development plans and policy implementation.

Although effective participation is not straightforward, and takes time to generate, it is nonetheless an important means by which to empower and build capacity in affected communities, enhance accountability, and improve the effectiveness of interventions. Therefore, as demonstrated in the following examples, participation has a positive impact on the enjoyment of the right to health.

In Peru in the 1980s, patients' associations, spontaneously set up in response to the government's failure to provide drugs and financial compensation for people who had suffered from leishmaniasis, were eventually successful in securing support from the regional and national health authorities. They became forums for discussions of wide-ranging social and political issues. This movement, which became more structured and organized over time, provided local institutions with detailed knowledge and made links with local populations so that it became possible to determine the best control and intervention strategies, and implement them successfully (Guthman et al. 1997, p. 17).

In Uganda, Village Health Teams are able to help dispel the neglect that characterizes certain diseases and populations, ensuring that local needs are clearly identified, understood, and addressed. Moreover, the Teams can provide the crucial grassroots delivery mechanisms for community interventions in relation to neglected diseases, and health protection generally (UNCHR 2006a).

Vehicles for community participation such as these require adequate resources, training, and support. They must be listened to and used strategically as delivery mechanisms in relation to neglected diseases, with smooth and effective coordination, cooperation, and collaboration between them and the local political structure and health centres. For this reason, government, development actors, and others should sustain and foster vital community-based initiatives to ensure that full and effective participation can support the realization of the right to health.

Monitoring and accountability

In practice, few accountability mechanisms give sufficient attention to neglected diseases, and often prove inaccessible to impoverished members of neglected communities. Within a national jurisdiction, parliamentarians might hold the Minister of Health to account in relation to the discharge of his or her responsibilities, yet the ability of these and other general mechanisms (such as judicial processes) to provide adequate accountability in relation to neglected diseases and the right to health is doubtful.

The right to the highest attainable standard of health demands accessible, transparent, and effective monitoring and accountability mechanisms that are meaningful to neglected communities. These could include independent national human rights institutions that monitor the incidence of neglected diseases and the initiatives taken to address them. Adopting an evidence-based approach, the institution could scrutinize who is doing what and whether or not they are doing all that can reasonably be expected of them to realize the right to health of those concerned. Whenever possible, the institution should identify realistic and practical recommendations for all those involved.

International human rights machinery can also draw attention to the issue of neglected diseases and neglected populations. For example, when a relevant State presents its periodic reports to CESCR, both the Government's reports and the human rights body's examination of them should give careful attention to the issue of neglected diseases and neglected populations, in accordance with the national and international right to health standards to which the Government is bound.

International assistance and cooperation

This feature of the right to health requires that donors and the international community pay particular attention to the health problems of the most vulnerable and disadvantaged individuals and communities in developing countries. For example, donors and the international community have a duty to help developing countries enhance their capacity so they can determine their own national and local health research and development priorities, such as neglected diseases.

Mental disabilities

Too often, disability issues do not attract the attention they demand and deserve. This is especially true in the context of mental disabilities, which include all major and minor mental illness and psychiatric disorders, as well as intellectual disabilities. The right to the highest attainable standard of health demands that due attention is given to both physical and mental disabilities.

A significant development in the field of disability was achieved with the adoption of a new international human rights treaty in 2006, the Convention on the Rights of Persons with Disabilities. Alongside this important new treaty, there are many important

provisions contained in non-binding principles that have profound connections to the right to health, such as the *UN Principles for the Protection of Persons with Mental Illness and the Improvement of Mental Health Care*, even if some elements are inadequate and need revisiting (UNGA 1991). Where appropriate, these specialized instruments should be used as interpretive guides in relation to the right to health as it is enshrined in international law.

International human rights treaties and specialized international instruments relating to mental disabilities are mutually reinforcing, even if, as the UN Secretary General recently put it, 'a more detailed analysis of the implementation of State human rights obligations in the context of mental health institutions would be desirable' (UNGA 2003, para. 43). Inadequate attention has been given to the implementation of these obligations to date. It is hoped that the new UN Convention will help to remedy this situation.

Freedoms and entitlements

Freedoms

Freedoms of particular relevance to the experience of individuals with mental disabilities include the right to control one's health and body. Forced sterilizations, rape, and other forms of sexual violence, to which women with mental disabilities are particularly vulnerable, are inherently inconsistent with their sexual and reproductive health rights and freedoms, are psychologically and physically traumatic, and thus jeopardize mental health even further.

Several international human rights instruments allow for exceptional circumstances in which persons with mental disabilities can be involuntarily admitted to a hospital or another designated institution (ECHR, Article 5 (1) (e); UN Mental Illness Principles, Principle 16). However, because involuntary detention is an extremely serious interference with the freedom of persons with disabilities, in particular their right to liberty and security, international and national human rights law attaches numerous procedural safeguards to involuntary detention cases. Moreover, these safeguards are generating a significant jurisprudence, most notably in regional human rights commissions and courts (ECtHR 1979; Gostin 2000; Lewis 2002; Gostin and Gable 2004).

Entitlements

The right to health includes an entitlement to a system of health protection which provides equality of opportunity for all people to enjoy the highest attainable standard of health through access to both healthcare and the underlying determinants of health, all of which play a vital role in ensuring the health and dignity of persons with mental disabilities (UNGA 1993, Rules 2–4).

States are required to take steps to ensure a full package of community-based mental healthcare and support services conducive to health, dignity, and inclusion. These should include medication, psychotherapy, ambulatory services, hospital care for acute admissions, residential facilities, rehabilitation for persons with psychiatric disabilities, programmes to maximize the independence and skills of persons with intellectual disabilities, supported housing and employment, income support, inclusive and appropriate education for children with intellectual disabilities, and respite care for families looking after a person with a mental disability 24 hours a day. In this way, unnecessary institutionalization can be avoided.

Scaling up interventions to ensure equality of opportunity for the enjoyment of the right to health requires that adequate numbers of appropriate professionals be trained. Similarly, primary care providers should be provided with essential mental health-care and disability sensitization training to enable them to provide front-line mental and physical healthcare to persons with mental disabilities.

Underlying determinants of health that are particularly relevant to persons with mental disabilities, who are disproportionately affected by poverty and as such often deprived of important entitlements, include adequate sanitation, safe water, and adequate food and shelter (UNCESCR 2000, para. 4). The conditions in psychiatric hospitals, as well as other institutions used by persons with mental disabilities, are often grossly inadequate from this point of view.

Obligations of immediate effect and progressive realization

It is reasonable to expect that countries, even those with very limited resources, undertake to implement certain measures towards realization of the right to health for people with disabilities. For example they can be expected to: include the recognition, care, and treatment of mental disabilities in training curricula of all health personnel; promote public campaigns against stigma and discrimination of persons with mental disabilities; support the formation of civil society groups that are representative of mental healthcare users and their families; formulate modern policies and programmes on mental disabilities; downsize psychiatric hospitals and, as far as possible, extend community care; in relation to persons with mental disabilities, actively seek assistance and cooperation from donors and international organizations (WHO 2001b, pp. 112–15).

Respect, protect, fulfil

Specifically in relation to mental disabilities, the obligation to *respect* requires States to refrain from denying or limiting equal access to healthcare services and underlying determinants of health, for persons with mental disabilities. They are also required to ensure that persons with mental disabilities in public institutions are not denied access to healthcare and related support services, or underlying determinants of health, including water and sanitation (IACHR 1997).

The obligation to *protect* means that States are required to take actions to ensure that third parties do not harm the right to health of persons with mental disabilities. For example, States should take measures to protect persons with mental disabilities from violence and other right to health-related abuses occurring in private healthcare or support services.

The obligation to *fulfil* requires States to recognize the right to health, including the right to health of persons with mental disabilities, in national political and legal systems, with a view to ensuring its implementation. States should adopt appropriate legislative, administrative, budgetary, judicial, promotional, and other measures towards this end (ICESCR Article 2(1); UNCESCR 2000, para. 36). For example, States should ensure that the right to health of persons with mental disabilities is adequately reflected in their national health strategy and plan of action, as well as other relevant policies, such as national poverty reduction strategies, and the national budget (WHO 2004B). Mental health laws, policies, programmes, and projects should embody human rights and empower people with mental disabilities to make choices about

their lives; give legal protections relating to the establishment of (and access to) quality mental health facilities, as well as care and support services; establish robust procedural mechanisms for the protection of those with mental disabilities; ensure the integration of persons with mental disabilities into the community; and promote mental health throughout society (WHO 2005). Patients' rights charters should encompass the human rights of persons with mental disabilities. States should also ensure that access to information about their human rights is provided to persons with mental disabilities and their guardians, as well as others who may be institutionalized in psychiatric hospitals.

International assistance and cooperation

The record shows that mental healthcare and support services are not a priority health area for donors. Furthermore, donors have sometimes supported inappropriate programmes, such as the rebuilding of a damaged psychiatric institution constructed many years ago on the basis of conceptions of mental disability that have since been discredited. In so doing, the donor inadvertently prolongs, for many years, seriously inappropriate approaches to mental disability.

It is unacceptable for a donor to fund a programme that, in moving a psychiatric institution to an isolated location, makes it impossible for its users to sustain or develop their links with the community (MDRI 2002). If a donor wishes to assist children with intellectual disabilities, it might wish to fund community-based services to support children and their parents, enabling the children to remain at home, instead of funding new facilities in a remote institution that the parents can only afford to visit once a month, if at all (Rosenthal et al. 2000).

Donors have a right to health duty to consider more—and better quality—support in the area of mental disability. In accordance with their responsibility of international assistance and cooperation, they are required to consider adopting measures such as: supporting the development of appropriate community-based care and support services; supporting advocacy by persons with mental disabilities, their families and representative organizations; and providing policy and technical expertise. Furthermore, donors should ensure that all their programmes promote equality and non-discrimination for persons with mental disabilities, while international agencies fulfil the role that corresponds to them by providing technical support.

Monitoring and accountability

The right to health requires that States have in place effective, transparent, and accessible monitoring and accountability mechanisms in relation to the health of persons with mental disabilities.

In many countries, there is an absence of sustained and independent monitoring of mental healthcare, resulting in frequent abuses in large psychiatric hospitals and community-based settings going unnoticed. The Mental Illness Principles emphasize the importance of inspecting mental health facilities, as well as investigating and resolving complaints where an alleged violation of the rights of a patient is concerned (UN Mental Illness Principle 22).

Lack of surveillance is doubly problematic because persons with mental disabilities, especially those who are institutionalized, are often unable to access independent and effective accountability mechanisms when their human rights have been violated. Where accountability mechanisms do exist, the severity of their condition

may render them unable to protect their interests independently through legal proceedings, to demand effective procedural safeguards where these may be lacking, or to access legal aid.

For example, the right to health requires that an independent review body must be made accessible to persons with mental disabilities, or other appropriate persons, to review cases of involuntary admission and treatment periodically (UN Mental Illness Principle 17).

Although there is a range of detailed international standards concerning the human rights of persons with mental disabilities, and procedural safeguards to protect them (UN Mental Illness Principles 11, 18), their lack of implementation poses a real challenge. The new Convention on the Rights of Persons with Disabilities will be crucial to international monitoring and accountability, especially if its Optional Protocol, which introduces a procedure under which individuals and groups can lodge complaints, were to come into force. Significantly, this mechanism strengthens the existing standards relating to the right to health of persons with mental disabilities that do not establish specific monitoring or accountability mechanisms.

Alongside this Convention, other international human rights treaties (including ICESCR, CRC, CEDAW and CERD, and ICCPR) extend protections to persons with mental disabilities. For this reason, States should pay greater attention to them in their State party reports, and examination of these reports by the human rights treaty bodies should, in turn, give a greater focus to these issues through their discussions with States parties, concluding observations, and general comments or recommendations. Relevant civil society organizations, including representatives of persons with mental disabilities, play an important role by engaging with UN treaty bodies and special procedures.

Sexual and reproductive health, including maternal mortality

The Commission on Human Rights confirmed in 2003 that ‘sexual and reproductive health are integral elements of the right of everyone to the enjoyment of the highest attainable standard of physical and mental health’ (UNCHR 2003b, preamble and para. 6). The outcomes of world conferences, in particular the International Conference on Population and Development (UN 1994), the Fourth World Conference on Women (UN 1995), and their respective 5-year reviews, confirm that human rights have an indispensable role to play in relation to sexual and reproductive health issues.

More recently, there has been a deepening conceptual and operational understanding of maternal mortality as a human rights issue (Freedman 2003; Ministry for Foreign Affairs 2006; UNHRC 2010a; Kaur 2012; Kismodi et al. 2012; UNOHCHR 2012b; Hunt and Gray 2013). Although the issue is connected to a number of human rights, the right to the highest attainable standard of health is of particular relevance, and is the focus of the following remarks.

Monitoring and accountability Freedoms

In the context of sexual and reproductive health, freedoms include a right to control one’s health and body. Rape and other forms of sexual violence, including forced pregnancy, non-consensual contraceptive methods (e.g. forced sterilization and forced abortion),

female genital mutilation/cutting (FGM/C), and forced marriage all represent serious breaches of sexual and reproductive freedoms, and are therefore fundamentally and inherently inconsistent with the right to health. In the specific context of maternal mortality, relevant freedoms include freedom from discrimination; harmful traditional practices, such as early marriage; and violence.

For example, some cultural practices, including FGM/C, carry a high risk of disability and death. This means that where the practice exists, States should take appropriate and effective measures to eradicate it, in accordance with their obligations under the Convention on the Rights of the Child. Early marriage, which disproportionately affects girls, is predominantly found in South Asia and sub-Saharan Africa, where over 50 per cent of girls are married by the age of 18. Among other problems, early marriage is linked to health risks including those arising from premature pregnancy. Finally, in the context of adolescent health, States are obliged to set minimum ages for sexual consent and marriage (UNCRC 2003, paras. 9, 19).

Entitlements

Entitlements that form part of the rights to reproductive and sexual health include equal access, in law and fact, to reproductive and child health services, as well as information about sexual and reproductive health issues.

Specifically, States are required to provide a wide range of appropriate and, where necessary, free sexual and reproductive health services, including access to family planning, pre- and post-natal care, emergency obstetric services, and access to information (Cottingham et al. 2012). They should also ensure access to such essential health services as voluntary testing, counselling, and treatment for sexually transmitted infections, including HIV/AIDS, and breast and reproductive system cancers, as well as infertility treatment.

Unsafe abortions kill some 68,000 women each year, and thus constitute a right to life and right to health issue of enormous proportions. They also give rise to high rates of morbidity. Women with unwanted pregnancies should be offered reliable information and compassionate counselling, including information on where and when a pregnancy may be terminated legally. Where abortions are legal, they must be safe: public health systems should train and equip health service providers and take other measures to ensure that such abortions are not only safe but accessible (WHO 2003). In all cases, women should have access to quality services for the management of complications arising from abortion. Punitive provisions against women who undergo abortions are inconsistent with the right to the highest attainable standard of health (UNGA 2011; Kismodi et al. 2012).

Certain entitlements envisaged in international law are directly relevant to reducing maternal mortality (CEDAW Article 12 (2); UNCESCR 2000, para. 14) and, if fulfilled, would reduce its incidence. For example, an equitable, well-resourced, accessible, and integrated health system—a crucial entitlement arising from the right to health—is widely accepted as a vital pre-condition for guaranteeing women’s access to the interventions that can prevent or treat the causes of maternal deaths (Freedman 2005). Other entitlements include education and information on sexual and reproductive health (UNCEDAW 1999, para. 18), safe abortion services where not against the law, and primary healthcare services (UN 1994, para. 8.25; UNCEDAW 1999, para. 27; UNCESCR

2000, paras. 14, 21), especially universal access to reproductive healthcare (UNMP 2005b).

The entitlement to specific underlying determinants of health relevant to maternal mortality must also be guaranteed. The failure to safeguard women's rights is often manifested in low status of women, poor access to information and care, early age of marriage, and restricted mobility, among other problems (DFID 2005). Specifically, gender equality has an important role to play in preventing maternal mortality as alongside empowerment it can lead to greater demand by women for family planning services, antenatal care, and safe delivery. Another relevant determinant of health and element of the right to health that must be ensured in order to address problems of maternal mortality is water and sanitation, which are vital to the provision of prenatal care and emergency obstetric care.

Available, accessible, acceptable, and good quality

In many countries, information on sexual and reproductive health is not readily available and, if it is, it is not accessible to all, in particular women and adolescents. Sexual and reproductive health services are often geographically inaccessible to communities living in rural areas, or provided in a form that is not culturally acceptable to indigenous peoples and other non-dominant groups. Similarly, services, and relevant underlying determinants of health, such as education, are often of substandard quality.

In order to address the problem of maternal mortality, the concept of availability calls for collective action to enhance care and improve human resource strategies, including increasing the number and quality of health professionals and improving terms and conditions (UNMP 2005c). Accessibility considers whether physical access and the cost of health services influence women's ability to seek care (UNMP 2005c). Furthermore, discriminatory laws, policies, practices, and gender inequalities prevent women and adolescents from accessing good quality services or information on sexual and reproductive health, and have a direct impact on maternal mortality (Cook et al. 2006). To prevent maternal mortality, scaling up technical interventions, or making the interventions affordable is insufficient: strategies ensuring the *acceptability* of services through their sensitivity to the rights, cultures and needs of pregnant women, including those from indigenous peoples and other minority groups, are also vital (Shiffman 2006). Quality of care will influence both a woman's decision whether or not to seek care, as well as the outcome of interventions, and so is key to tackling maternal mortality through the provision of maternal healthcare services.

Discrimination, vulnerability, and stigma

Discrimination and stigma continue to pose a serious threat to sexual and reproductive health for many groups, including women, sexual minorities, refugees, people with disabilities, rural communities, indigenous persons, people living with HIV/AIDS, sex workers, and people held in detention. Some individuals suffer discrimination on several grounds, e.g. gender, race, poverty, and health status (UNCHR 2003a, para. 62).

Discrimination based on gender hinders the ability of many women to protect themselves from HIV infection and to respond to the consequences of HIV infection. Women and girls' vulnerability to HIV and AIDS is compounded by other human rights issues including inadequate access to information, education, and services necessary to ensure sexual health; sexual violence;

harmful traditional or customary practices affecting the health of women and children (such as early and forced marriage); and lack of legal capacity and equality in areas such as marriage and divorce.

Stigma and discrimination associated with HIV/AIDS may also reinforce other prejudices, discrimination, and inequalities related to gender and sexuality. The result is that those affected may be reluctant to seek health and social services, information, education, and counselling, even when those services are available. This, in turn, will contribute to the vulnerability of others to HIV infection.

Vulnerability in the context of sexual and reproductive health is particularly relevant to adolescents and young people, who find themselves lacking access to relevant information and services during a period characterized by sexual and reproductive maturation. Important protections for adolescents are enshrined in CRC, which includes a number of cross-cutting principles which have an important bearing on adolescents' sexual and reproductive health, namely: the survival and development of the child, the best interests of the child, non-discrimination, and respect for the views of the child (CRC Articles 2, 3, 5, 6, and 12; UNCRC 2003, para. 12).

Discrimination on the grounds of sexual orientation is impermissible under international human rights law. The legal prohibition of same-sex relations in many countries, in conjunction with a widespread lack of support or protection for sexual minorities against violence and discrimination, impedes the enjoyment of sexual and reproductive health by many people with lesbian, gay, bisexual, and transgender identities or conduct (UNCHR 2001, paras. 48–50; UNGA 2001, paras. 17–25; UNHRC 2010c, para. 6–26). Similarly, criminalization can impede programmes which are essential to promoting the right to health and other human rights (UNHRCtee 1994, para. 8.5).

Arising from their obligations to combat discrimination, States have a duty to ensure that health information and services are made available to vulnerable groups. For example, they must take steps to empower women to make decisions in relation to their sexual and reproductive health, free of coercion, violence, and discrimination. They must take action to redress gender-based violence and ensure that there are sensitive and compassionate services available for the survivors of gender-based violence, including rape and incest. States should ensure that adolescents are able to receive information, including on family planning and contraceptives, the dangers of early pregnancy, and the prevention of sexually transmitted infections including HIV/AIDS, as well as appropriate services for sexual and reproductive health. Consistent with *Toonen v. Australia* and numerous other international and national decisions, they should ensure that sexual and other health services are available for men who have sex with men, lesbians, and transsexual and bisexual people. It is also important to ensure that voluntary counselling, testing, and treatment of sexually transmitted infections are available for sex workers (UNHRCtee 1994).

Finally, in the context of sexual and reproductive health, breaches of medical confidentiality may occur. Sometimes these breaches, when accompanied by stigmatization, lead to unlawful dismissal from employment, expulsion from families and communities, physical assault, and other abuse. Also, a lack of confidentiality may deter individuals from seeking advice and treatment, thereby

jeopardizing their health and well-being. States are obliged to take effective measures to ensure medical confidentiality and privacy.

Water and sanitation

Healthcare attracts a disproportionate amount of attention and resources. Yet access to water and sanitation, as well as other underlying determinants of health, are integral features of the right to the highest attainable standard of health.

Available, accessible, acceptable, and quality

Available

The right to health requires a State to do all it can to ensure that safe water and adequate sanitation are available to everyone in its jurisdiction. The quantity of water available for each person should correspond to the quantity specified by WHO (Howard and Bartram 2002), though some individuals and groups may require additional water due to health, climate, and work conditions, and the State should therefore ensure that this is also available. The right to health stipulates that States must ensure the availability of safe water for personal and domestic uses such as ‘drinking, personal sanitation, washing of clothes, food preparation, personal and household hygiene’ (UNCESCR 2003 para. 12 (a)).

Accessible

The right to health also requires that water and sanitation be accessible to everyone without discrimination. In this context, accessibility has four dimensions.

First, water and sanitation must be within safe physical reach for all sections of the population, in all parts of the country. Water and sanitation therefore should be *physically accessible* within, or in the immediate vicinity of, the household, educational institution, workplace, and health or other institution (UN 2005, guideline 1.3). The inaccessibility of water within safe physical reach can seriously impair health, including the health of women and children responsible for carrying water. Carrying heavy water containers for long distances can cause fatigue, pain, and spinal and pelvic injuries, which may lead to problems during pregnancy and childbirth. Similarly, the absence of safe, private sanitation facilities subjects women to a humiliating, stressful, and uncomfortable daily routine that can damage their health (UNMP 2005a, pp. 23–5). When designing water and sanitation facilities in camps for refugees and internally displaced persons, special attention should be given to prevent gender-based violence. For example, facilities should be provided in safe areas near dwellings (UNHCR 2005).

Second, water and sanitation should be *economically accessible*, including to those living in poverty. Poverty is associated with inequitable access to health services, safe water, and sanitation. If those living in poverty are not enjoying access to safe water and adequate sanitation, the State has a duty to take reasonable measures that ensure access to all.

Third, water and sanitation should be *accessible* to all *without discrimination* on any of the grounds prohibited under human rights law, such as sex, race, ethnicity, disability, and socioeconomic status.

Finally, reliable *information* about water and sanitation must be *accessible* to all so that they can make well-informed decisions.

Acceptable

The right to health requires that water and sanitation facilities be respectful of gender and life-cycle requirements and be culturally

acceptable. For example, measures should ensure that sanitation facilities are mindful of the privacy of women, men, and children.

Quality

Both water services and sanitation facilities must be of good *quality*: this reduces susceptibility to anaemia, diarrhoea, and other conditions that cause maternal and infant mortality and morbidity (UNMP 2005a, p. 18). Water required for personal and domestic use should be safe and free from ‘micro-organisms, chemical substances and radiological hazards which constitute a threat to a person’s health’ (UNCESCR 2003, para. 12(b)). States should establish water quality regulations and standards on the basis of the *WHO Guidelines for Drinking Water Quality* (WHO 2006b).

Similarly, each person should have affordable access to sanitation services, facilities, and installations adequate for the promotion and protection of their human health and dignity. Good health requires the protection of the environment from human waste; this can only be achieved if everyone has access to, and utilizes, adequate sanitation (UNCHR 2004, para. 44).

In 2008, the UN Human Rights Council appointed a Special Rapporteur on the human right to safe drinking water and sanitation whose reports shed light on the contours and content of this important human right (UNHRC 2010b).

New tools and techniques

The ‘Human rights’ section introduced the idea, which is increasingly recognized, that one way of vindicating the right to the highest attainable standard of health is by way of the ‘policy approach’ i.e. the integration of the right to health in national and international policymaking approaches. For this approach to prosper, the traditional human rights techniques—taking test cases in the courts, ‘naming and shaming’, letter-writing campaigns, slogans, and so on—will not be sufficient. The ‘policy approach’ demands the development of new right-to-health skills and tools, such as budgetary analysis, indicators, benchmarks, and impact assessments. In recent years, the health and human rights community has made significant progress towards the development of these new methodologies. Here, by way of illustration, indicators, benchmarks, and impact assessments are briefly introduced in the context of the right to the highest attainable standard of health.

A human rights-based approach to health indicators

The international right to the highest attainable standard of health is subject to progressive realization. Inescapably, this means that what is expected of a State will vary over time. With a view to monitoring its progress, a State needs a device to measure this variable dimension of the right to health. The most appropriate device is the combined application of indicators and benchmarks. Thus, a State selects appropriate indicators that will help it monitor different dimensions of the right to health. These indicators might include, for example, maternal mortality ratios and child mortality rates. Most indicators will require disaggregation, such as on the grounds of sex, race, ethnicity, rural/urban, and socioeconomic status. Then the State sets appropriate national targets or benchmarks in relation to each disaggregated indicator.

In this way, indicators and benchmarks fulfil two important functions. *First*, they can help the State to monitor its progress over time,

enabling the authorities to recognize when policy adjustments are required. *Second*, they can help to hold the State to account in relation to the discharge of its responsibilities arising from the right to health, although deteriorating indicators do not necessarily mean that the State is in breach of its international right to health obligations (UNCHR 2006b, para. 35). Of course, indicators also have other important roles. For example, by highlighting issues such as disaggregation, participation, and accountability, indicators can enhance the effectiveness of policies and programmes.

Health professionals and policy makers constantly use a very large number of health indicators, such as the HIV prevalence rate. Is it possible to simply appropriate these health indicators and call them ‘human rights indicators’ or ‘right to health indicators’? Or do indicators that are to be used for monitoring human rights and the right to health require some special features? If so, what are these special attributes?

The considered view is that some of these health indicators may be used to monitor aspects of the progressive realization of the right to health, provided the following conditions are met (UNGA 2004):

1. They correspond, with some precision, to a right to health norm.
2. They are disaggregated by at least sex, race, ethnicity, rural/urban, and socioeconomic status.
3. They are supplemented by additional indicators—rarely found among classic health indicators—that monitor five essential and inter-related features of the right to health:
 - ◆ A national strategy and plan of action that includes the right to health.
 - ◆ The participation of individuals and groups, especially the most vulnerable and disadvantaged, in relation to the formulation of health policies and programmes.
 - ◆ Access to health information, as well as confidentiality of personal health data.
 - ◆ International assistance and cooperation of donors in relation to the enjoyment of the right to health in developing countries.
 - ◆ Accessible and effective monitoring and accountability mechanisms.

In this way, many existing health indicators, such as the maternal mortality ratio and HIV prevalence rate, have an important potential role to play in measuring and monitoring the progressive realization of the right to health, provided that they conform to these conditions (Hunt and MacNaughton 2007; UNOHCHR 2012a).

Impact assessments and the right to the highest attainable standard of health

A further tool that can be employed to monitor the fulfilment of the right to health and hold duty-bearers to account is through impact assessments. They are an aid to equitable, inclusive, robust, and sustainable policymaking, and have the objective of informing decision-makers and the people likely to be affected by a new policy, programme, or project so that the proposal can be improved to reduce potential negative effects and increase positive ones. They are one way of ensuring that the right to health—especially

of marginalized groups, including the poor—is given due weight in all national and international policymaking processes. From the right to health perspective, an impact assessment methodology is a key feature of a health system and an essential means by which a government can gauge whether or not it is on target to realize progressively the right to health.

At least two distinct methodological approaches are available: to develop a self-standing methodology for human rights impact assessments such as has been done in other fields, such as environmental and social policy; or to integrate human rights into *existing* types of impact assessments. The second approach is consistent with the call on governments to mainstream human rights into all government processes and requires interdisciplinary collaboration (MacNaughton and Hunt 2009).

In order that an impact assessment uphold rights-based principles, it must: (1) use an explicit human rights framework, (2) aim for progressive realization of human rights, (3) promote equality and non-discrimination in process and policy, (4) ensure meaningful participation by all stakeholders, (5) provide information and protect the right to freely express ideas, (6) establish mechanisms to hold the State accountable, and (7) recognize the interdependence of all human rights (MacNaughton and Hunt 2011).

If the second approach is adopted, there are six steps that should be followed to ensure that the right to health is integrated into existing impact assessments: (1) perform a preliminary check on the proposed policy to determine whether or not a full-scale right-to-health impact assessment is necessary; (2) prepare an assessment plan and distribute information on the policy and the plan to all stakeholders; (3) collect information on potential right-to-health impacts of the proposed policy; (4) prepare a draft report comparing the potential impacts with the State’s legal obligations arising from the right to health; (5) distribute the draft report and engage stakeholders in evaluating the options; and (6) prepare the final report detailing the final decision, the rationale for the choices made, and a framework for implementation and evaluation.

Overall, the human rights framework for impact assessment adds value because human rights: (1) are based on legal obligations to which governments have agreed to abide; (2) apply to all parts of the government, encouraging coherence to policymaking and ensuring that policies reinforce each other; (3) require participation in policymaking by the people affected, enhancing legitimacy and ownership of policy choices; (4) enhance effectiveness by demanding data disaggregation, participation, and transparency; and (5) demand mechanisms through which policy makers can be held accountable.

Conclusion: key features of a health system from a right to health perspective

The right to the highest attainable standard of health can be understood as a right to an effective and integrated health system, encompassing healthcare and the underlying determinants of health, which is responsive to national and local priorities, and accessible to all.

At the heart of this understanding of the right to health is a package of health services, facilities, and goods, extending to healthcare and the underlying determinants of health, such as

access to safe water, adequate sanitation, and health-related information. This package must be available, accessible, and of good quality. Also, it must be sensitive to different cultures. While this package will have many features that are common to all countries, there will also be differences between one country and another, reflective of different disease burdens, cultural contexts, resource availability, and so on. This chapter has signalled some elements of this package in relation to neglected diseases, mental disability, sexual and reproductive health, and water and sanitation.

However, besides this essential package of health services, facilities, and goods, a health system must have some additional features if it is to reflect the right to the highest attainable standard of health (Backman et al. 2008). These additional features derive from international norms, including CESCR's General Comment 14 on the right to the highest attainable standard of health. While some of these additional features have been described in the preceding paragraphs, they include the following:

1. Formal legal recognition of the right to health in either a national Constitution, or bill of rights, or other statute.
2. An elaboration of what the right to health means, for both the public and private sectors, for example by way of regulations, guidelines, and codes of conduct.
3. Research and development for national and local health priorities.
4. A comprehensive situational analysis identifying, *inter alia*, the health needs of the population, upon which (5) is based.
5. A comprehensive national health plan, including objectives, timeframes, who is responsible for what, reporting procedures, indicators and benchmarks (to measure progressive realization), and a detailed budget.
6. A health financing system that is equitable and evidence-informed.
7. An ex-ante right to health impact assessment methodology that permits the Government to foreshadow the likely impact of a draft law, policy, or programme on the enjoyment of the right to the highest attainable standard of health, thereby enabling it, when necessary, to revise the projected initiative.
8. As much 'bottom-up' participation as possible, in relation to policymaking, implementation, and accountability.
9. Access to health-related information and data; data will have to be disaggregated so that the health situation of disadvantaged populations is properly understood, enabling the authorities to devise measures that address health inequities and disadvantage; at the same time, however, arrangements must be in place to ensure that personal medical data remains confidential.
10. As well as effective mechanisms for coordination within the health sector, there must also be effective mechanisms for inter-sectoral coordination in health, because the right to health extends beyond the health sector; moreover, where relevant, there must be effective coordination and referral with traditional health systems.
11. A sufficient number of domestically trained health workers enjoying good terms and conditions of employment; they should be reflective of the country's cultural diversity, including language, and strike a balance between men and women; health workers' training should include human rights.
12. An international dimension, for example, low-income countries should seek international assistance and cooperation in health and high-income countries should provide it.
13. Educational campaigns and other arrangements so that the public knows about its right to health entitlements and how to vindicate them.
14. Effective, transparent, and accessible monitoring and accountability mechanisms, including redress, for both the public and private health sectors.

States have a legal obligation to ensure that their health systems not only include an appropriate package of health services, facilities, and goods, but also the additional features briefly summarized in points 1–14.

A key challenge for the future is to conduct multidisciplinary and multimethod research on the evidence of impact of human rights on health (Bustreo et al. 2013).

Key points

- ◆ The right to the highest attainable standard of health is enshrined in several international treaties and numerous national constitutions.
- ◆ It gives rise to legally binding obligations on States.
- ◆ There is a complementary relationship between public health and the right to the highest attainable standard of health.
- ◆ The right to health analytical framework deepens understanding of contemporary public health issues and can help to identify appropriate responses to them.
- ◆ The right to the highest attainable standard of health can be understood as a right to an effective and integrated health system, encompassing healthcare and the underlying determinants of health, which is responsive to national and local priorities, and accessible to all.

Law and the public's health

Lawrence Gostin

Introduction to law and the public's health

Public health law can be defined as the legal powers and duties of government, in collaboration with multiple partners (e.g. health-care, business, the community, the media, and academe), to assure the conditions for people to be healthy and safe (to identify, prevent, and ameliorate risks to health in the population). The prime objective of public health law is to pursue the highest possible level of physical and mental health in the population, consistent with the values of social justice (Gostin 2008).

Although government needs adequate power to safeguard the public's health, it should not interfere with the civil rights and liberties of individuals without adequate justification. Government therefore has limitations—both legal and ethical—in exercising power that constrains the autonomy, privacy, liberty, proprietary, or other legally protected interests of individuals. Some of the most challenging, and enduring, debates in public health law are the conflicts between individual liberties and the common good.

Public health laws have deep roots in social history, ranging from the ancient use of quarantines at land and at sea, to sanitary laws in the wake of the Industrial Revolution, through to injury prevention, and non-communicable disease (NCD) control in the late twentieth century. Domestic public health laws operate at the local (e.g. municipal codes) and national level. Often, federalist states such as Brazil, Canada, India, and the United States have complex constitutional arrangements between local, regional, and national public health laws.

Domestic public health laws and regulations also intersect with international health law (e.g. the International Health Regulations and Framework Convention on Tobacco Control), 'soft' law (e.g. World Health Organization (WHO) codes of practice and global strategies), and wider international regimes that impact on health (e.g. trade, migration, human rights, and the environment). The complex intersections between local, national, and international law to protect the public's health cannot be overemphasized.

This chapter first examines the powers and duties of government to protect the public's health and safety, together with the limits on its authority to protect a sphere of individual rights and liberties. Second, it explores the central value of public health law—social justice, with particular attention to unconscionable inequalities in health based on socioeconomic status. Third, the chapter examines the statutes and regulations that create public health agencies—defining their mission, powers, funding, and scope. Fourth, the chapter categorizes seven legal 'tools' at the state's disposal to promote the health, safety, and well-being of the

population: taxing and spending, the informational environment, the built environment, the socioeconomic environment, direct regulation, indirect regulation, and deregulation. Finally, the chapter turns to how legal interventions can be used to prevent or ameliorate three major health hazards: infectious diseases, NCDs, and injuries (both unintentional and intentional).

Public health: powers, duties, and limits

Governments have the power and duty to safeguard the public's health and safety. The international human right to health, which virtually all countries accept as part of treaty obligations, imposes on governments the primary responsibility for the public's health. In many newer democracies (for example, in Africa and Latin America), national constitutions also guarantee the right to health, as well as other socioeconomic rights such as the right to life and to a safe environment (Friedman and Gostin 2012). Emerging economic powers such as Brazil, India, and South Africa have had robust 'right to health' litigation in their judicial systems. Whether through international law or national constitutions, the state's highest obligation is the defence of the social and economic well-being of the population, with health and security being among the most vital. In most theories of democracy health and security are seen as quintessential aspects of the social contract between individuals and their governments (Walzer 1983).

Beyond socioeconomic rights, virtually all states around the world—older constitutions such as in the United States, newer ones such as in South Africa, and even those without written constitutions such as the United Kingdom—protect civil and political rights—for example, bodily integrity, privacy, liberty, and non-discrimination. At the same time, national constitutions, as well as public health laws, also usually afford individuals civil and political rights, which can constrain the power of ministries to use compulsion. Provided that agencies act for an important public health purpose, and use means that are proportionate to the ends, they can require conformance with publicly established standards of conduct.

Protecting and preserving the public's health and safety is often not possible without constraining a range of private activities that pose unacceptable risks. Private actors can profit by engaging in practices that damage the rest of society: individuals can spread infectious disease; industry has a profit motive, which can result in unsafe workplaces, environmental pollution, or unhealthy products. Some industries are inherently dangerous (e.g. tobacco), while others can have harmful effects (e.g. alcoholic beverages). In

each instance, individuals or organizations act in their own interests, but their actions may adversely affect communal health and safety. In the absence of governmental authority and willingness to coerce, such threats to the public's health could not easily be reduced.

Although regulation in the name of public health is intended to safeguard the health and safety of whole populations, it often benefits those most at risk of injury and disease. Everyone gains value from public health regulations, such as food and water standards, but some regulations protect the most vulnerable. For instance, eliminating a toxic waste site, enforcing a building code in a crowded tenement, or closing an unhygienic restaurant holds particular significance for those at immediate risk. Frequently, those at increased risk are particularly vulnerable due to their race, gender, or socioeconomic status.

Individuals and businesses often oppose government regulation. Resistance is sometimes based on philosophical grounds of autonomy, choice, or freedom from government interference. Citizens, and the groups that represent them, claim that regulating self-regarding behaviour, such as the use of seat belts or motorcycle helmets, is not the business of government. Or they harbour suspicions about government's intent, such as fluoridation of drinking water. Public health agencies sometimes have to defend charges of paternalism, or the 'Nanny State,' such as with Mayor Bloomberg's decision to limit portion size of sugary drinks in New York City (Gostin and Gostin 2009).

Public health has historically constrained the rights of individuals and businesses to protect community interests in health. Reporting and surveillance diminish privacy; mandatory testing, vaccination, and treatment invade bodily integrity; environmental standards reduce property values; industrial regulation impedes economic freedom; and isolation and quarantine deprive individuals of liberty. In each of these cases, and more, public health has not shied from regulating individuals and businesses for the common good.

Public health powers can legitimately be used to restrict human freedoms and rights, but they must be exercised consistent with constitutional and statutory constraints on state action. Governments cannot over-reach, such as constraining liberty without sufficient evidence of public benefit. When agencies coerce they must do so proportionately, such as by using the least restrictive measure needed to avert the health threat. And they must always act fairly, without discrimination on grounds such as race, gender, or disability. Achieving a just balance between the powers and duties of the state to advance the public's health and constitutionally protected rights poses an enduring challenge for public health law.

Social justice

Social justice is viewed as so central to the mission of public health that it has been described as the field's core value: 'The historic dream of public health... is a dream of social justice' (Beauchamp 1999, p. 105). Among the most basic and commonly understood meanings of justice is fair, equitable, and appropriate treatment in light of what is due or owed to individuals and groups (Rawls 1971).

Social justice captures the twin moral impulses that animate public health: to advance human well-being by improving health

and to do so particularly by focusing on the needs of the most disadvantaged (Gostin and Powers 2006). This account of justice has the aim of bringing about the human good of health for all members of the population. An integral part of that aim is the task of identifying and ameliorating patterns of systematic disadvantage that profoundly and pervasively undermine prospects for well-being of oppressed and subordinated groups—people whose prospects for good health are so limited that their life choices are not even remotely like those of others (Powers and Faden 2006). These two aspects of justice—health improvement for the population and fair treatment of the disadvantaged—create a richer understanding of public health law and ethics. Seen through the lens of social justice, the central mission of the public health system is to engage in systematic action to assure the conditions for improved health for all members of the population, and to redress persistent patterns of systematic disadvantage.

Imagine a government policy designed to reduce tobacco consumption in the population. If the government were to lower the smoking prevalence from, say, 30 per cent to 15 per cent, would that be acceptable if marginalized groups such as institutionalized populations (e.g. prisoners and mental patients) continue to have high smoking prevalence? What if the government explicitly targets smoking prevention messages to the well-off but not in poor neighbourhoods? Is that acceptable as a matter of social justice?

These are the quintessential values of public health law—government power and duty, coercion and limits on state power, and the value of social justice. To achieve the goals of population health under the rule of law requires sound legal foundations. Statutes and regulations—as interpreted by the judicial system—establish the infrastructure for public health agencies ranging from their mission, functions, and powers, to their organization and funding.

Public health statutes: legal foundations of public health agencies

The field of public health is typically regarded as a scientific endeavour, and undoubtedly our understanding of the aetiology and response to disease is heavily influenced by technical inquiry. Less well understood is the role of law in public health. Law defines the jurisdiction of public health officials and specifies the manner in which they may exercise their authority. Public health statutes create public health agencies, designate their mission and core functions, appropriate their funds, grant their power, and limit their actions to protect a sphere of freedom. They authorize the collection of health information and enable monitoring and regulation of dangerous activities. The most important public health debates take place in legal forums—legislatures, courts, and administrative agencies—and in the law's language of rights, duties, and justice (Grad 2004).

The quality and modernity of public health laws around the world are highly variable (Institute of Medicine 2011). Some states have relatively recent and comprehensive public health laws; others have older statutes, while still others have virtually no public health laws. Overall, public health statutes often have a number of deficiencies. They may be quite old, reflecting an era when infectious and sexually transmitted infections were the major

health hazards. They can be highly fragmented, built up in layers over time, for example, beginning with tuberculosis and sexually transmitted diseases (e.g. syphilis and gonorrhoea), through to polio and then AIDS, and more recently traffic safety and diet and physical activity. These laws may not afford the state sufficient authority to protect the public's health and safety and they may fail to adequately protect individual rights and freedoms. For example, many older statutes do not ensure natural justice or procedural due process before the exercise of compulsory powers.

Given the importance of sound, modern public health laws, many (if not most) states should examine the corpus of their public health laws and regulations. Low- and middle-income countries may need the capacity and knowledge to reform their laws. The influential Institute of Medicine in the United States issued a major report on public health law reform in 2011, urging states to adopt the 'Turning Point' Model Public Health Act (Hodge et al. 2006). That model act could provide a template for other countries. Additionally, the WHO and International Development Law Organization are planning to release a 'Public Health Law Manual' that would provide law reform guidance particularly in low- and middle-income countries.

The WHO Constitution requires member states to notify the Organization of its major public health statutes and regulations, even though few states actually comply. The WHO publishes a *Health Law Digest*, but the Organization has drastically cut back resources for the *Digest*. The Director-General's reorganization several years ago removed 'law' from the title of the department charged with publishing the *Digest*. Today, the *Digest* is solely in electronic form and has lost its utility to provide a systematic account of national public health laws.

The lawmaking process: building constituencies and forming partnerships

The methods and goals of public health are often misunderstood and undervalued within government and society. Public health needs opportunities to draw attention to its resource requirements and its achievements so that it can develop constituencies for programmes. The lawmaking process provides such an opportunity. A bill is the first step towards a coalition. It is an occasion for contact with interest groups and affected communities, some of whom may be motivated to act in support of the bill. Contacts and collaborative efforts also help to establish long-term ties and identify important sources of support for other programmes. Moreover, the process of negotiating for support can be a useful and concrete way for health agencies to incorporate the views of persons who receive public health services or are subject to regulation.

Legal reform also has the potential to enhance health agencies' relationships with the legislature. Positive lawmaking offers a different sort of contact with legislators than tends to occur in the appropriations process. Public health law reform may offer an occasion to deal with a far greater range of legislators outside the context of contentious budget discussions. The drafting, negotiating, and hearing processes provide a variety of forums for educating lawmakers and their staffs about public health needs and methods and also provide health planners with better information about legislative views and priorities.

Law reform, of course, cannot guarantee better public health. However, by crafting a consistent and uniform approach, carefully delineating the mission and functions of public health agencies,

designating a range of flexible powers, and specifying the criteria and procedures for using those powers, the law can become a catalyst, rather than an impediment, to reinvigorating the public health system.

Models of legal interventions: law as a tool for the public's health

Law can be empowering, providing innovative solutions to the most implacable health problems. Many of the great public health achievements in the twentieth century were realized, at least in part, through law reform or litigation, including vaccinations, safer workplaces, safer and healthier foods, motor vehicle safety, control of infectious diseases, tobacco control, and fluoridation of drinking water (Centers for Disease Control and Prevention 2000).

The study of public health law, therefore, requires a detailed understanding of the various legal tools available to prevent injury and disease and to promote the health of the populace. There are a number of models for using law as a tool for the public's health and safety, including: taxation and spending, the informational environment, the built environment, the socioeconomic environment, direct regulation, indirect regulation through the tort system, and deregulation. Although in each case the law can be a powerful agent for change, the interventions can also raise critical social, ethical, or constitutional concerns (Gostin 2008).

Model 1: the power to tax and spend

The power to tax and spend—the quintessential governmental function found everywhere—provides government with an important regulatory technique. Most governments invest in a broad array of services to promote public health ranging from surveillance to education and research. Although funding is far too limited, many governments spend to establish and maintain a public health infrastructure consisting of: a trained workforce, electronic information and communications systems, rapid disease surveillance, laboratory capacity, and response capability. In some states, governments can attach 'conditions' to public spending that are intended to be health promoting. For example, in the United States, the federal government requires states to have a drinking age of 21 years as a condition of the receipt of highway funds.

The power to tax is primarily designed to raise revenue, but it also can provide significant inducements to engage in beneficial behaviour and disincentives to engage in risk activities. Tax relief can be offered for health-producing activities such as healthcare services, childcare, and charitable contributions. At the same time, tax burdens can be placed on the sale of hazardous products such as cigarettes, alcoholic beverages, and firearms. Of course, taxation can create perverse incentives such as tax relief for the purchase of unsafe and fuel-inefficient motor vehicles. A carbon tax offers a good example of an economic vehicle that would be beneficial to the public's health and the environment.

Model 2: the power to alter the informational environment

The public is constantly exposed to images and information that influence their life choices, and this undoubtedly affects health

and behaviour. The reliability and usefulness of information is variable. Some messages are educational, such as child nutrition campaigns. Other information can be biased—either inaccurate or misleading. For example, the corporate profit motive can result in advertisement of harmful products, such as foods with excess sugar and salt. Messages such as ‘low fat,’ ‘low calorie,’ or ‘light’ can be confusing or deceptive.

Regulating the flow in information can be challenging. In practical terms, governments do not have the available resources to compete with large advertising budgets that market unhealthy foods, alcoholic beverages, or tobacco. In constitutional terms, there can be questions about whether advertising restrictions violate the corporation’s right to free expression.

Governments have several tools at their disposal to alter the informational environment thereby encouraging people to make more healthful choices about diet, physical activity, tobacco, and alcohol. First, government, as a health educator, can use communication campaigns that warn consumers of high risks (e.g. smoking or driving while intoxicated) or encourage safer activities (e.g. wearing seat belts or motorcycle helmets). Second, government can require businesses to label their products to inform consumers: instructions on safe product use, disclosure of contents or ingredients, or warnings about hazards. Third, government can regulate advertising and promotions for potentially harmful products such as cigarettes and firearms. They can also limit marketing certain products to vulnerable populations, such as children and adolescents.

Regulating tobacco packaging and advertising offers a good illustration. The WHO’s Framework Convention on Tobacco Control (WHO 2005a) requires states to adopt supply and demand reduction strategies, including advertising restrictions. Yet, the tobacco industry has challenged advertising restrictions and packet labels in countries as diverse as Australia, Uruguay, and the United States. Australia was the first country to introduce plain packaging legislation with graphic images of the harms of tobacco. Although Australia’s highest court upheld the legislation, the government is defending its law both in an Investment Treaty dispute and at the World Trade Organization (*British American Tobacco Australia Limited v. The Commonwealth* 2012). Uruguay’s tobacco control legislation is also being challenged in a separate Investment Treaty case (*FTR Holding v. Oriental Republic of Uruguay* 2010). ‘Big Tobacco’ is claiming that the state is unfairly ‘taking’ their property or diminishing the value of their private investments. Although this may seem to be an outrageous claim, it is expensive for states to defend their public health laws.

In the United States, the Food and Drug Administration’s requirement of graphic warning labels is going to be decided by the Supreme Court. Tobacco companies are claiming that the graphic image requirement violates their rights to free expression (*R.J. Reynolds Tobacco Company v. Food and Drug Administration* 2012). The United States is one of the world’s outliers in that its highest court ardently defends the right of corporations to free expression, thus thwarting public health restraints on advertising hazardous products.

Model 3: the power to alter the built environment

The design of the ‘built’ or ‘physical’ environment can hold great potential for creating healthier and safer communities. Public

health has a long history of altering the built environment to reduce injuries (e.g. workplace safety, traffic calming, consumer protection, and fire codes), infectious diseases (e.g. sanitation, nuisance abatement, and housing codes), and environmentally associated harms (e.g. lead paint and toxic emissions). Sanitary laws go back hundreds of years, designed to ensure more hygienic conditions in growing cities; occupational health and safety became prominent following the Industrial Revolution, which exposed workers to toxins and unsafe working conditions; and more modern laws provide patients and consumers with protection against unsafe products.

The epidemiological transition from infectious to chronic diseases raises new challenges in the design of neighbourhoods. For example, urban design can encourage more active lifestyles (walking lanes, bicycle paths, parks, green fields, and playgrounds); improve nutrition (zoning to limit fast food); discourage the use of hazardous products (‘tobacco-free’ indoor spaces); reduce violence (well-lit streets, safe storage of firearms); and increase social interactions (helping neighbours and building social capital) (Perdue et al. 2003).

Many zoning laws in the mid and late twentieth century were unfavourable to healthy lifestyles, such as those giving preference to motor vehicles over pedestrians and bicycle riders, or preferring commercial development over playgrounds. Municipalities often facilitated the expansion of unhealthy fast foods, forming ‘food deserts’ in poor neighbourhoods. These are political choices, and debates still rage over whether government should use health as a major factor in designing living spaces, rather than, say, economic development. What seems certain is that it is within the power of government to structure the environment in ways that are more conducive to a healthy diet and physical activity.

Model 4: the power to alter the socioeconomic environment

A strong and consistent finding of epidemiological research is that socioeconomic status (SES) is correlated with morbidity, mortality, and functioning (Marmot 2005). SES is a complex phenomenon based on income, education, and occupation. The relationship between SES and health often is referred to as a ‘gradient’ because of the graded and continuous nature of the association; health differences are observed well into the middle ranges of SES. These empirical findings have persisted across time and cultures and remain viable today.

Some researchers go further, concluding the overall level of economic inequality in a society correlates with (and adversely affects) population health. That is, societies with wide disparities between rich and poor tend to have worse health status than societies with smaller disparities, after controlling for per capita income. These researchers hypothesize that societies with higher degrees of inequality provide less social support and cohesion, making life more stressful and pathogenic. Drawing upon this line of argument, some ethicists contend, ‘social justice is good for our health’ (Daniels et al. 2000).

The WHO issued a report on social determinants of health, urging more attention to the underlying factors in influencing health outcomes (WHO 2008b). However, the WHO never put significant resources into social determinants and did not follow the Commission Report with international law or softer norms. From government’s perspective, ensuring a healthy population that is

fair and equitable requires an 'all of government,' indeed 'all of society' approach that transcends the health sector.

Although social determinants powerfully affect health, they can require redistribution of wealth and hence are often hotly contested. Opponents of redistributive policies argue such policies punish personal accomplishment, thereby discouraging economic growth. Still, it is impossible to make significant inroads into health disparities without careful attention to the deeper social and economic determinants of health.

Model 5: direct regulation of persons, professionals, and businesses

Government has the power to directly regulate individuals, professionals, and businesses. In a well-regulated society, public health authorities set clear, enforceable rules to protect the health and safety of workers, consumers, and the population at large.

Regulation has long been a staple of injury control. In most Western countries, for example, the rate of motor vehicle-related injuries and deaths has plummeted due to law reform. Governments required individuals to engage in safer behaviour, such as by using seat belts and motorcycle helmets. The law also compelled manufacturers to design and sell safer vehicles, such as cars with airbags and with the ability to better withstand crashes. The law also set standards for governmental and commercial development such as safer roads and traffic calming. Yet, with the explosion of motorized vehicles in newly emerging states, the injury and death rates from motor vehicles are alarming. The streets of Bangkok, Delhi, and Hanoi (among many others) are teeming with unsafe vehicles, chaotic roads, and motorcycle drivers and passengers without helmets.

Perhaps the most ancient use of direct public health regulation is in the control of infectious diseases. Governments often mandate vaccination, screening, partner notification, directly observed therapy, and isolation or quarantine. Originating from the ancient scourges such as leprosy, malaria, and tuberculosis, through to syphilis and herpes, and to the modern AIDS pandemic, states—for good or bad—have enacted civil and criminal laws to deter or punish perceived risk behaviours. Early in the AIDS pandemic, for example, many states enacted laws to require testing (e.g. prisoners), travel and immigration restrictions, and even quarantine (e.g. Cuba). Criminal laws were altered to punish behaviours conducive to transmitting HIV, and to targeting risk populations such as injecting drug users and commercial sex workers.

Direct regulation also plays a major role in ensuring that professionals and businesses operate safely and with the requisite level of skill and knowledge. Licences and permits enable government to monitor and control the standards and practices of healthcare professionals, hospitals, and nursing homes. By licensing and accrediting health professionals, public health agencies can help ensure safe, competent, and well-qualified practitioners. Finally, inspection and regulation of businesses helps to assure humane conditions at work, reduced toxic emissions, and improved consumer product safety.

The control of chronic diseases is becoming the new battleground over the wisdom of direct regulation. Some jurisdictions have banned harmful ingredients such as trans fatty acids; others have reduced harmful additives, such as excess sugar or sodium; while still others have regulated portion size, such as the size of a

sugary soft drink. Recent research suggests, 'sugar is toxic', which may require public health agencies to set or recommend safer levels of sugar intake (Basu et al 2013).

When regulating what people eat or their physical activity, governments often face the stinging criticism that they are acting paternalistically, with the charge of running a 'Nanny State'. To public health advocates, these are all necessary measures to make health the 'easier' or 'default' choice. But to many in society, it restricts their freedoms to make their own decisions about their health and well-being (Gostin and Gostin 2009).

Model 6: indirect regulation through the tort system

Ministries of justice and health, as well as private citizens, possess a powerful means of indirect regulation through the tort system. Civil litigation can redress many different kinds of public health harms: environmental damage (e.g. air pollution or groundwater contamination), exposure to toxic substances (e.g. pesticides, radiation, or chemicals), hazardous products (e.g. tobacco or firearms), and defective consumer products (e.g. children's toys, recreational equipment, or household goods).

The most prominent illustration of using judicial remedies for a public health purpose is tobacco litigation. Tort litigation against the tobacco industry began in the United States. This litigation had multiple benefits. It resulted in a 'Master Agreement' between states and tobacco companies, with large sums given to states. It uncovered highly damaging evidence about the deceptive behaviour of the industry, such as raising the nicotine level of cigarettes, hiding information about the hazards of smoking, and targeting young girls, racial minorities, and minors with cigarette advertisements and promotions.

More modern litigation has been waged under the constitutional right to health in places such as India and Latin America. Public health advocates in these and other countries have sued tobacco companies for knowingly misleading the public. They have also sued their own governments to force them to adopt more rigorous tobacco control measures, such as clean air acts (Cabrera and Gostin 2011).

Perhaps it would be predictable for Big Tobacco to use the law as a sword against government regulation. Increasingly, the industry is using the constitutional right to property or commercial speech, bilateral investment treaties to safeguard their investments, or World Trade Organization treaties to stall or block tobacco control (Mitchell and Studdert 2012).

Using tobacco litigation as a model, public health advocates have sought to use tort law to attack the deceptive and harmful practices of other powerful industries. This litigation ranges from lawsuits against the food industry (e.g. marketing unhealthy products to minors), the firearms industry (e.g. trafficking in dangerous weapons), and the alcohol industry (e.g. glamorizing underage or excessive drinking). Thus far, many of these lawsuits have not been successful. One difference is that food, firearms, and alcoholic beverages when used responsibly are not harmful, while tobacco use is always hazardous.

To what extent should the harmful activities of these and other industries be immune from tort litigation on the theory that autonomous consumers are free to make their own decisions—whether healthful or harmful? Given that individuals are embedded in communities and societies that profoundly affect their

personal choices, laws should enable consumers to litigate if the private sector has exposed them to unnecessary and serious risks.

Model 7: deregulation: law as a barrier to health

Sometimes laws are harmful to the public's health and stand as an obstacle to effective action. In such cases, the best remedy is deregulation. Politicians may urge superficially popular policies that have unintended health consequences. Consider laws that prohibit or penalize needle exchange programmes and pharmacy sales of sterile syringes. Even though access to sterile injection equipment significantly reduces the risk of needle-borne infections (e.g. HIV and hepatitis B or C) and does not encourage illicit drug use, many governments discourage or ban the distribution of these products, including by public health agencies.

A further illustration is the decision to close bathhouses, making it more difficult to reach gay men with condoms and safe sex literature. Rather than banning these activities, government could use them as venues for education and harm reduction.

Finally, but perhaps even more importantly, governments throughout the world criminalize high-risk activities. They punish sex workers, drug users, and even those who engage in same-sex sexual activities. Criminal laws that punish activities that risk transmission of HIV, for example, do not appear to reduce unsafe behaviour, but rather drive the epidemic underground.

Criminal law is usually a blunt, ineffective, and unfair tool when used for an allegedly public health purpose. Deregulation, however, can be controversial because it often involves a direct conflict between public health and other values that society may favour, such as crime prevention or morality. Drug laws, the closure of bathhouses, and HIV-specific criminal penalties represent society's disapproval of disfavoured behaviours. Deregulation becomes a symbol of weakness that is often politically unpopular. Public health advocates may believe passionately in harm-reduction strategies, but the political community may want to use the law to demonstrate social disapproval of certain activities such as illicit drug use, commercial sex, or unprotected sex.

The government, then, has many legal 'levers' designed to prevent injury and disease and promote the public's health—taxing and spending, the informational environment, the built environment, the socioeconomic environment, direct regulation, indirect regulation, and deregulation. Legal interventions can be highly effective and need to be part of the public health officer's arsenal. However, legal interventions can also be controversial, raising vital ethical, social, constitutional, and political concerns.

Case studies of four major health hazards

The previous sections often used major health hazards as illustrations of the use of public health law. This chapter concludes with four brief case studies: infectious diseases, NCDs, unintentional injuries, and violence to self or others. This final section shows how the intersection between public health law at the local, national, and international levels can influence health outcomes.

Infectious disease law

As mentioned earlier, infectious disease law has ancient origins (Markel 2005). Epidemic disease has historically had profound

implications, not only for animal and human health, but also for security, trade, tourism, and social relationships. Infectious diseases often bring out the worst in people and societies, provoking stigma and discrimination against disfavoured groups such as immigrants and ethnic or religious minorities. Rapidly emerging diseases (such as novel influenzas) often provoke unjustified trade or travel restrictions. At the same time, governments are likely to spend disproportionate public health resources on highly transmissible or novel infections—disproportionate at least insofar as infectious pathogens receive so much more attention than equally destructive health hazards, such as NCDs, injuries, and mental illness.

This dynamic can be seen in the emphasis in domestic and international laws on infectious diseases. The oldest international health law—dating from mid-nineteenth-century sanitary conferences in Europe—is the International Health Regulations, which are devoted almost exclusively to health security. The one and only time the International Health Regulations (WHO 2005b) were used was in relation to the influenza A (H1N1) pandemic. Before that, governments were planning and spending large resources on novel influenzas, in response to H5N1.

The emphasis on epidemic diseases can also be seen in domestic law, where most public health statutes are devoted to infectious disease powers, such as testing, screening, partner notification, directly observed therapy, and isolation or quarantine. During the SARS outbreaks, states—particularly in North America and Asia—exercised public health powers extensively including travel restrictions, trade barriers, border security, and quarantine (Fidler 2004).

Even in the realm of international relations, infectious diseases have dominated funding and political attention. The AIDS pandemic fundamentally changed the political and funding calculus for global health. The United States launched the greatest effort by a single country against a single disease—PEPFAR. The United Nations (UN) formed a new agency to coordinate work on AIDS—UNAIDS. And powerful new public/private partnerships emerged to provide unprecedented funding for work on AIDS, tuberculosis, and malaria, such as the Global Fund and UNITAID, while the GAVI Alliance supports another infectious disease initiative—immunizations. Most impressively, the international community has vastly ramped up research, funding, and access to antiretroviral treatment for HIV/AIDS.

Non-communicable disease law

Four NCDs—cardiovascular disease, cancer, respiratory disease, and diabetes—account for 63 per cent of global deaths annually. The conventional wisdom, which conceives of NCDs as a 'First World' problem, is starkly belied by data: 80 per cent of the 35 million people who die annually from NCDs live in low- and middle-income countries. The death toll is projected to rise by 17 per cent over the next decade, unless meaningful steps are taken urgently. With the exception of sub-Saharan Africa, NCD mortality now exceeds that of infectious, maternal, perinatal, and nutritional conditions combined (WHO 2011).

The suffering and early deaths from NCDs, and the disproportionate burden in lower-income countries, will only grow. And they will interact with existing health challenges in poorer countries, creating the 'double burden' of hunger alongside obesity. Although longer lifespans partly explain the increased burden

of NCDs, human behaviour plays a central role: unhealthy diets, sedentary lifestyles, smoking, and excessive alcohol consumption account for more than two-thirds of all new NCD cases.

The moral tragedy lies in the fact that much of this suffering and early death is preventable, and many of the solutions are to be found in law—at both the domestic and international levels. Local and national governments have all the public health law tools at their disposal in fighting the NCD epidemic. They can tax unhealthy products such as tobacco, alcoholic beverages, sugary drinks, and sodium-laden processed foods. Equally, rich states could cease subsidizing unhealthy foods, such as high-fructose corn syrup, cane sugar, and even red meat and dairy, while subsidizing healthy fruits and vegetables.

Governments can also alter the informational environment, counteracting incessant commercial messages—for example by package labelling, health warnings on cigarettes and alcohol, and comprehensible nutritional information on food packages and restaurant menus. The United Kingdom Food Standards Agency developed a voluntary system ‘traffic light’ system that is visible and simple to follow. By putting a series of bright red lights on food packages with excessive saturated or trans fats, sodium, sugar, and calories, it incentivizes food companies to be more responsible, while clearly informing consumers. The state can restrict advertising unhealthy products, particularly when aimed at minors (Hawkes 2007).

Individual choices are not made in isolation, but reflect the environment in which people live. Government could use its powers to plan cities and zones to facilitate healthy lifestyles, including supermarkets and farmers’ markets. It can build bike and walking paths, designate pedestrian areas, subsidize mass transit, and discourage motor vehicle use—such as the ‘congestion tax’ instituted by the city of London in the United Kingdom. Government could require ‘health impact assessments’ as a condition of new government or commercial development.

Although incentives and voluntary approaches are often more politically palatable, there is also a role for direct regulation. Some products, such as trans fatty acids, are so hazardous to health that they should be removed from the market, as Denmark has done (see Table 3.4.1).

It is equally important to marshal a transnational response. The impact of globalization—globalized food and tobacco markets and the homogenization of cultures and behaviours—means that no country can effectively tackle NCDs without the support and cooperation of the international community. Global governance for health requires a multifaceted approach (Gostin 2014). The international community could set norms for healthy activities, such as the Framework Convention on Tobacco Control (WHO 2005a). The WHO has also developed ‘Global Strategies’ covering: NCD prevention and control (2000); diet, physical activity, and health (2008); and the harmful use of alcohol (2010). In 2008, the Assembly adopted the 2008–2013 Action Plan for its Global Strategy on NCDs, and in 2010, it adopted recommendations on the marketing of foods and non-alcoholic beverages to children (WHO 2008a, 2010).

The decade of WHO governance on NCDs failed to raise NCDs to the same high profile and impact as HIV/AIDS. But the UN General Assembly (2011) hosted a high-level meeting on NCDs in September 2011, adopting a *Political Declaration on the Prevention and Control of Non-Communicable Diseases*—a 65-point

document, cataloguing many of the global challenges, and calling for a whole-of-government/whole-of-society response. Broadly speaking, the Declaration recommends preventative measures, health system strengthening, international cooperation, research and development, and monitoring and evaluation of progress. Sadly, however, the UN failed to set clear targets, a tangible road-map to meet those targets, and the resources needed to tackle the global NCD pandemic.

Just as domestic governments need to adopt an ‘all-of-government/all-of-society’ approach, so too must global institutions look beyond WHO to a more expansive view of governance. In short, there is a need for ‘total global engagement,’ encompassing trade, investment, development, intellectual property, and human rights—all international law regimes in their own right. The private sector is a vital part of the solution, but the major companies operate all over the world, so corporate governance must also operate at the global, as well as the national, level.

Injury control law

Injuries are often portrayed as ‘accidents’ or ‘random events’ that are unpredictable and therefore unpreventable, as opposed to a serious public health concern, which explains the field’s historical neglect. However, injuries are a leading cause of death and disability worldwide, resulting in nearly 6 million deaths annually and representing 17 per cent of the global burden of disease; by 2020 the global burden of injuries is projected to increase to 20 per cent (WHO 2011). The injury epidemic has been compounded by rapid unplanned urbanization, increased motorization, and dramatic changes in the built environment in low- and middle-income countries (Lozano et al. 2012; Murray et al. 2012; Salomon et al. 2012).

There are marked inequalities in the global distribution of injuries, with >90 per cent of all deaths and disability-adjusted life years occurring in low- and middle-income countries, mostly among young people. The economic burdens for those countries are staggering: traffic incidents alone cost \$65 billion or 1–1.5 per cent of GDP annually (Norton et al. 2006).

The WHO differentiates between unintentional injuries (no predetermined intent such as road traffic incidents, poisonings, falls, fires, and drowning) and intentional injuries (self-directed such as suicide or self-mutilation, interpersonal such as domestic violence or murder, or collective violence such as war-related injuries). Law reform can help prevent both of these.

The UN Convention on the Rights of the Child (UN 1989) guarantees all children the right to a safe environment and to protection from injury and violence. Yet, injuries are the single greatest cause of death and disability among children in low- and middle-income countries. Drowning is a leading cause of morbidity and premature mortality in children under 5 years of age. With increasing age, mortality resulting from road traffic crashes surpasses that from drowning, with traffic deaths being the greatest overall killer of children aged 15–19.

Men often suffer injuries in the course of paid labour or occupational pursuits, while women suffer burns as a result of their customary domestic role—in the kitchen, from fires or scalding water, and as a result of cooking on open fires. The home use of kerosene or paraffin lamps, which are easily knocked over and ignited, is also a large contributor. Above all, underlying gross poverty heavily influences many of these injuries, irrespective of age and gender.

Table 3.4.1 Domestic strategies to address NCD risk factors

Domain	Goal	Intervention	Example
Healthy lifestyles	Optimal nutrition	Agricultural production	Incentives to produce healthier foods
		Food manufacturing, processing, and distribution	Regulation of food industry and retailers
		Disincentives for buying and selling unhealthy food	'Fat tax'
		Marketing unhealthy foods	Restricting advertisements targeting children
		Nutritional information disclosure and education	Providing government nutritional guidelines; improving package labelling; menu labelling
		Direct regulation	Banning unhealthy ingredients (such as trans fats)
		Public-private partnership	Voluntary targets for nutritional values
	Physical activity	Incentives for exercise	Subsidies for physical exercise and organized activities
		Flexible spending accounts	Corporate allowances for fitness activities
		Monitor community physical activity	Public health surveillance of monitoring prevalence of NCDs
Healthy places	Places to buy and eat food	Access to affordable, healthy foods	Farmers' markets; zoning of unhealthy fast foods
		Healthy foods in schools, workplaces, etc.	Vending machines, snacks, meals
		School/childcare curricula and programmes	Body mass index (BMI) surveillance; nutrition education
	Places to walk, recreate, and play	Workplace/education settings and programmes	Organized activities; fitness memberships
		Urban land use and planning	Attractive, accessible, safe public places and paths
		Tax incentives for building design	Businesses incorporating building designs that promote physical activity
		Transportation	Mass transit and safe routes
Healthy societies	Social justice	Health impact assessments	Consultation with affected communities; public health evaluations
	Access to services	Antidiscrimination laws	Proscribe medical condition-related discrimination
		Services to support life functions of ill individuals	At-home support services
		Encourage prevention and treatment	Metabolic screening; counselling
		Monitoring disease in the community	Surveillance through BMI reporting

National public health laws are perhaps the single most potent interventions to prevent injuries. Developed countries have used a multitude of regulations to vastly curtail traffic injuries and deaths—e.g. driving licences, speed limits, vehicle safety, motorcycle helmets, and road design. Yet, in many low- and middle-income countries, the roads are chaotic and very dangerous, with vehicles unfit for travel and roads poorly planned. The mix of pedestrians, bicycles, and motorized vehicles on unsafe roads that do not separate the types of traffic is lethal. To further compound the problem, roadways are usually designed with the convenience of the drivers in mind and little thought for the safety of pedestrians. In Nairobi, residents of Kibera, one of the largest urban slums in the world, suffer inordinate road traffic injuries and deaths, as they have to run across dangerous roads to get to work, school, or shops to buy food and clothing.

Work-related injuries are ubiquitous in low-resourced countries. The rise in industrial development and the lack of attention to safety will ensure that occupational injuries double by 2025. Again, this situation is very different in the developed world, which has steadily decreased occupational injury rates over the years. Most industrial work in low-resourced countries such as

agriculture, manufacturing, and mining is already associated with high rates of injury from electrical, mechanical, and physical hazards. Now, the steady expansion of chemical and biotechnology industries has introduced new injury risks.

Yet, occupational health and safety laws cover only 10 per cent of the population in low-resourced countries. Without adequate regulations, businesses do not invest in quality equipment or train workers to ensure safety. Companies often expect workers to take inordinate risks because labour is cheap and plentiful. If developing countries do not soon implement effective safety standards, the health costs to workers in high-risk jobs will outweigh the financial benefits of industrial development.

Intentional injuries are also a vast and growing problem, particularly in low- and middle-income countries. Rates of robberies, assaults, rapes, and homicides can be devastating in major cities such as Johannesburg. India has experienced an epidemic of gender-related violence, which also occurs in many other parts of the world. In some African countries, gay men are subjected to brutal assaults and murders. Yet, it is possible to prevent most injuries through technological innovation, safety regulation, and law enforcement. However, the same ingenuity and resources that

make the home, workplace, and the streets safer in richer countries have not been applied in low-resourced countries. The WHO devotes <1 per cent of its budget to injuries and violence.

Developed countries, of course, are not immune from violence, which could be dramatically lowered with sound firearm regulation and enforcement. In the United States, for example, firearm-related deaths are roughly equal to road traffic deaths, with few checks on gun buyers or the lethality of weapons and bullets.

If the public health community wishes to close the 'injury gap' between rich and poor, it will have to devise evidence-based solutions, demonstrate their effectiveness, engage the private sector, gain the cooperation of police and the courts, devote the resources, and advocate for strong occupational health and safety laws throughout the developed world.

Conclusion: the future of public health law reform

This chapter has sought to demonstrate the powerful potential of law to prevent injuries and disease. Law can build the infrastructure of public health agencies, ensuring a broad mission and adequate powers. It can protect individuals from excessive or unjustified coercion or discrimination. It can promote social justice by narrowing health disparities. At the same time, government has multiple legal tools available to improve the public's health and safety, ranging from its economic power to tax and spend, to its authority to alter the environments in which people live (e.g. informational, built, and socioeconomic), through to direct and indirect regulation, including, where necessary, deregulation.

With the potential for rapid dissemination of pathogens, products, services, and marketing throughout the world, the need for global governance cannot be overstated. No country acting alone can stem the tide of injuries and disease. Global health leadership could establish health-promoting norms, set benchmarks, monitor progress, and encourage compliance by state and non-state actors. Global leadership, moreover, must act beyond the health sector, engaging legal regimes such as trade, intellectual property, food, migration, and the environment.

When law is used in a systematic and coordinated way at the local, national, and international levels, it can go a long way towards preventing infectious diseases, NCDs, and injuries (both unintentional and violence-related). For public health practitioners, the lesson is to effectively use the battery of legal tools at their disposal. And when those tools are inadequate, public health agencies must work with civil society and communities to raise the level of political awareness. In a complex and globalized world, public health is a deeply legal and political pursuit—well beyond purely science and technology.

Priority setting, social values, and public health

Peter Littlejohns, Sarah Clark, and Albert Weale

Introduction to priority setting, social values, and public health

Around the world, policymakers are facing the dilemma of how to allocate resources to healthcare in ways that are both effective and that can be justified to their citizens in terms of fairness and appropriateness. In the United Kingdom, the National Institute for Clinical Excellence (NICE, currently the National Institute for Health and Care Excellence) was created in 1999 in order to provide recommendations for medical care based on appraisals of cost-effectiveness evidence. NICE recommendations include explicit advice on which medical interventions should, and which should not, be offered to patients in a predominantly public healthcare system. Similar bodies now exist in France, Germany, Thailand, and South Korea. In Latin America, constitutional courts have been used by plaintiffs denied access to care as a means to enforce a right to health included in the constitutions of Columbia and Brazil. Even in the United States, which has long been a country hostile to explicit priority setting, the Affordable Care Act, passed by the Obama administration in 2011, established the Patient-Centered Outcomes Research Institute to provide evidence about the effectiveness of medical interventions in the context of the long-standing and persistent concerns about lack of cost-control in US health spending. The proposed institutional solutions vary from country to country; but the underlying problem of how best to allocate healthcare resources to good effect and in ways that can be publicly justified is common and pervasive.

Cost pressures on healthcare resources arise from a number of causes that are well understood in general terms, although the relative contribution of each is subject to dispute. People are living longer, not only increasing population size but also creating populations that are older. Citizens have rising expectations of health services and the quality of life that those services should deliver. Innovation in healthcare technology means that some very expensive pharmaceutical interventions, like NovoSeven®, a second-order treatment for haemophilia, are made available for relatively small groups of patients whose treatment may be very costly on a 'per case' basis. Alternatively, some pharmaceuticals, like statins, turn out to be relevant to a wider group of patients, contributing a large total increase in spending. As a result of these pressures, rising expenditure means that healthcare needs are in competition with one another and healthcare itself is in

competition with other potential uses of the same resources. In 1980 a typical west European state would spend 6–8 per cent of its national income on healthcare; in 2009 the equivalent figure was between 10 and 12 per cent of national income. In the same period, expenditure in the United States rose from approximately 9 per cent of national income to over 16 per cent. In virtually all developed societies, workers take half a day a week of their working life just to pay for healthcare, and in the United States it is closer to a day a week.

Public health has traditionally been concerned with such matters as the protection of populations from widespread communicable diseases or the promotion of healthy living as a means of prevention. It is sometimes contrasted with medical care, understood as the provision of diagnostic and therapeutic treatments to individuals in need. Public health is targeted at populations; medical care is targeted at individuals. This difference matches the distinction that economists make between public goods and private goods. Pure public goods, like clean air or water, are non-competitive, because they are available to everybody who falls within their scope. No one can be excluded from the benefit they supply, and their provision raises general social well-being. By contrast, private goods, like hip operations or cataract surgery, necessarily involve a competitive element. Resources made available for some individuals mean that there are fewer resources for other individuals. Priority setting in health policy is a problem of allocating healthcare resources, thought of as private goods, in a fair and efficient way. The typical issues that fall under the heading of priority setting include such questions as to whether to pay for highly expensive pharmaceutical products that provide only a few extra weeks or months of low-quality life, or whether to prioritize a small number of people in great need compared to a larger number of people in modest need.

The contrast between public goods, which have traditionally been the focus of public health, and medical interventions, which should be thought of as private goods, might suggest that problems of priority setting for medical care are not relevant for the study of public health. Because medical care inevitably involves allocating resources among patients according to an order of priority, much of the work of policymaking concerns the process of priority setting. By contrast, implementation of public health measures makes it possible to secure a gain for all, since members of a population are not in competition with one another for the same resource, and individual interventions may benefit others

through externalities or ‘spill-over’ effects. A vaccination programme will benefit all members of a population by reducing the risk of contagion. Clean water supplies will benefit all those who have access to them. Better road design will reduce the risk of accidents for all, just as good building standards will protect against the effects of disasters.

However, although there is a contrast between the competitive character of resource allocation in medicine on the one hand and the non-competitive measures aimed at improving public health on the other, the principles and practices of priority setting are nonetheless relevant to public health for a number of reasons. Firstly, public health measures involve spending resources, and so raise exactly the same questions about their priority as does provision for sickness. For example, vaccination programmes cost money as do public health education campaigns on such matters as smoking, obesity, and sexual health. Medicines stocked for preventive health reasons are a call on the budget in the same way that therapeutic medicines are a call on the budget. A concern for priorities inevitably raises the question of whether the money spent on these programmes provides better value than the alternative uses to which it could be put.

There is often perceived to be a potentially large gain for health budgets if effective public health measures can be undertaken. Effective control of tobacco, or reductions in the number of people who are obese, would save the medical services money, it is sometimes asserted, because it would reduce the number of people who would have to be treated. The evaluation of this claim is not straightforward, because if effective public health measures prolong life, their consequence may simply be to postpone costs onto the treatment and care of the degenerative diseases of old age. However, this point offers a good illustration of the way in which traditional public health concerns and priority setting concerns interact.

Since no country can afford to provide all its residents with every possible medical or public health intervention, all health systems face the problem of how to set priorities in the allocation of resources. These decisions cannot be made simply by appealing to technical tests of ‘what works’ because measuring what works inevitably involves a set of value judgements. Even something as seemingly technical as a satisfactory clinical outcome presupposes that quality of life is satisfactory and such a judgement is not purely technical. Moreover, priority setting decisions can be politically controversial. When NICE decided in 1999 not to recommend Relenza® within the National Health Service, its manufacturers, then Glaxo Wellcome, even spoke about relocating its production facilities outside of the United Kingdom in retaliation. Priority setting in healthcare inevitably means looks at the social values that are part of the civic and political cultures of different societies.

‘Social values’ is a term with no agreed precise definition. In this chapter we use it to designate the reasons that are used in policy deliberation that involve reference to those features of the content and processes of decision-making to which the members of a society attach importance. Such features may concern the decision-making process itself, for example, its transparency, or the content of the decision that is made, for example, whether it meets the entitlements to care that people are thought to have. In relation to these values, we can ask both how such considerations are taken into account in priority-setting processes and whether

there are some values that ought to be given greater weight in decision-making.

How are values in play?

Setting priorities is undertaken at many different levels of decision-making, ranging from the highest level of policy, where governments allocate overall national budgets or decide on reimbursement schemes for intervention, through the local level, as administrations balance delivering public health and clinical services to their communities, to the individual bed-side level where practitioners make decisions affecting individuals. Priority setting in healthcare is also not unique to governments. It is always apparent in commercial insurers’ decisions about the limits of coverage. It is also implicit in the priorities that non-governmental organizations and philanthropic foundations give to some interventions over others. In every case, we can ask what are the social values implicated in the decisions that are made.

The most important development in recent years is that a number of countries have developed specific institutions or agencies to advise on cost-effectiveness and priority setting and to provide the evidence upon which they aim to assess value for money in healthcare. These agencies include: the National Evidence-Based Healthcare Collaborating Agency (NECA) in Korea; the Health Improvement and Technology Assessment Programme (HITAP) in Thailand; the new Instituto de Evaluación Tecnológica en Salud (IETS) in Columbia, established in September 2012; the National Institute for Health and Care Excellence (NICE) in the United Kingdom; the recently established Patient-Centered Outcomes Research Institute in the United States; the Haute Autorité de Santé (HAS) in France; and the Institut für Qualität und Wirtschaftlichkeit im Gesundheitswesen (IQWiG) in Germany (Littlejohns et al. 2012a).

All agencies such as these face the problem of how to integrate social values into their decision-making on health priority setting. For example, in Thailand HITAP has confronted difficult questions about what should be included in its basic package of care. In particular, in a case of diapers for adult incontinence, a decision was required that paid attention to income distribution considerations, since the cost of diapers was absorbing a high proportion of the budget for poor households (see case study in Table 3.5.1).

Along with other systems, the Korean National Health Insurance system is facing the challenges of increased expenditure associated with an ageing population. In one example, the Korean health technology assessment (HTA) agency, NECA, had to deal with the case of glucosamine for osteoarthritis in the elderly, which raised questions about how to assess the value of a product for which there was little evidence of effectiveness, but which occupied a special position in the gift culture of the society. Ahn et al. have described the way in which pharmaceuticals, medical devices, diagnostics, and procedures are assessed in South Korea and shown how issues of accountability are of concern to stakeholders (Ahn et al. 2012).

HTA agencies in Europe are similarly challenged by how to take into account social values in their policymaking. Even for a well-established agency such as NICE in the United Kingdom, which has sophisticated decision protocols and a formalized approach to cost-effectiveness, unforeseen social values consequences of ‘technical’ decisions can challenge those decisions

Table 3.5.1 Social values and health priority setting case study

Title of case study	Absorbent Products for Adult Disabled and Elderly Incontinence in Thailand
Author	Dr Sarah Clark, School of Public Policy, UCL Dr Utsana Tomayakul, Health Intervention and Technology Assessment Programme (HITAP), Thailand
Author contact	s.l.clark@ucl.ac.uk
Date of Submission	11 July 2012
Case summary (approx. 350 words) Please include information here about why the case is of particular interest	This case concerns ‘adult diapers’ on which many elderly and disabled people in Thailand rely to enable them to cope with the problem of incontinence. Currently these products must be purchased by individuals or by households at some cost (an estimated \$1200 per year). The imposition of such costs on groups who are already vulnerable and socially disadvantaged raises issues of equity and solidarity. Despite being proven to be well below the Thai cost-effectiveness threshold and decision-makers recognizing the important solidarity values implied in the case, the products were not ultimately included in the Universal Coverage package on the grounds of the large numbers of those eligible for coverage, leading to a budget impact which was considered unacceptably high.
Facts of the case Please include information on as many of the following as are relevant to the case: <ul style="list-style-type: none"> • At what condition is the intervention, programme, or service aimed? • What are its effects? E.g. Is it curative, preventative, palliative, life-prolonging, rehabilitative? • Is there a relevant comparator? If so how does this intervention, service or program compare to the alternative? Include ICER estimates/QALY costs if relevant. • What are the significant features about the condition and/or about the patient population in this case? E.g. patient population is very young, very old, condition is rare, life-threatening, life-limiting, etc. • How are the benefits of the intervention distributed across the patient population and/or across time? • What is the cost or budget impact of the intervention/service/programme? 	<p>The use of absorbent products—‘diapers’—is necessary on a daily basis for those with incontinence, often occurring as a result of age or disability. Without these products, the quality of life of people with incontinence is impaired, and normal life hindered in a significant way. Catheterization is an alternative approach to incontinence but carries the risk of complications. Currently in Thailand, absorbent products are purchased privately. However given the daily, ongoing use of these products, their cost can be considerable for the elderly or disabled and for the families who support them. It has been estimated by a HITAP (Health Intervention and Assessment Program) assessment that on average families spend around \$1200 (37,000 Thai Baht) per year on these products and that around 360,000 people need to use them (Tantivess et al. 2012).</p> <p>To put these costs in perspective and to give an indication of affordability, in Thailand the average teacher annual net income is 192,000 THB, that of a dentist/GP is 375,000 THB, and that of a bus driver is 96,000 THB. The cost of these absorbent products, at least for lower-income families, is therefore likely to form a significant portion of household expenditure.</p> <p>A HITAP assessment estimated that provision of adult diapers to disabled people with incontinence produced a positive and statistically significant 32 per cent improvement in quality of life scores of over 10 weeks. The cost-effectiveness of including provision of adult diapers for the disabled within the Universal Coverage package was estimated at \$1200 per QALY or 37,000 Thai Baht.</p>

and provide cause for revising and modifying policy. For example, NICE has modified its technical guidance in respect of the threshold ICER to deal with considerations around treatments for patients at the end of their life and for children.

Similarly, the Haute Autorité de Santé in France, an established HTA agency, had to determine the value of a growth hormone, both in terms of how to assesses ‘normal’ height and how to balance risks against benefits, leaving them with a decision involving issues of social values as profound as how to define ‘normal’. In Germany, IQWiG has to make its decisions against the background of the German Constitutional Court decision in the 2005 *Nikolaus* case, according to which the individual judgement of a treating physician concerning the effectiveness of a treatment has to be respected and the health insurance system cannot deny reimbursement, thus demonstrating a deep commitment to the principle of clinical need which may on occasion conflict radically with considerations of cost-effectiveness (Bundesverfassungsgerichts 6, 2005).

In other parts of the world, the challenges of social values are worked out in very different ways. Recent developments in Latin

America have seen the growth of a rights-based approach to health and, in particular, an increase in the use of the courts to press for accountability in cases where individuals believe they have been denied equitable access to healthcare and their ‘right’ to health thereby violated. Cases brought to court on the basis of the right to health in countries such as Columbia and Brazil, have become known as ‘tutelas’ and have arisen as a consequence of a legal procedure known as a writ of protection, in the context of the constitutional changes that followed democratization in such countries (Cubillos et al. 2012). However, while court decisions in ‘tutelas’ may provide accountability in individual cases, this does not mean that the cumulative effect of such decisions is necessarily to move towards a more equitable system of care for the population as a whole. How social values are played out when national bodies decide on individual cases can thus be very different and not indicative of how they are played out at the level of policymaking as it affects the wider population.

These brief examples show that there are many common challenges faced by different decision-making systems but the ways in

which social values are brought into play, and the ways in which their challenges are dealt with, varies considerably. One example of this is the contrasting decision processes of the United Kingdom and Germany in respect of high-cost health interventions: in the United Kingdom, NICE explicitly uses quality-adjusted life years (QALYs) in determining priorities, whereas German HTA regards their use as incompatible with Germany's Basic Law. Social values thus help define the policy paradigm of different countries. A policy paradigm is defined by the basic concepts that are used in policy deliberation and such paradigms are embodied in institutional processes of decision in different countries (see Weale 2010 for a recent summary). Policy paradigms shape the way in which problems are understood, and the definition of what counts as success for a policy.

Despite the need for prioritization, formal approaches to addressing the challenge have so far not been as successful as hoped. There are a number of reasons:

1. More emphasis has been placed on the technical assessment of efficiency as manifested by the increasing number of national HTA programmes and less attention directed to issues of equity.
2. Compared to the amount of effort put into creating the evidence base for making prioritization decisions, little effort has been targeted at understanding the relationship between the outputs of HTA organizations and the political process of translating this evidence into national policy and then implementing that policy. Priority setting should aim to produce an allocation of healthcare resources that can be ethically justified, especially to those who lose out as a result of resource allocation decisions. Such an ethical justification requires articulation of social value judgements, both in terms of the process of decision-making, on which allocation decisions rest, and in terms of the content of those decisions. Such a justification is a vital element in any public legitimization of how priorities are set. Yet there are legitimate disagreements about which social value should dominate as they can be contradictory. To date, most attempts of adding dimensions other than efficiency have relied on creating lists of values with little emphasis on how these could actively inform real decisions (Culyer and Bombard 2012; Johri and Norheim 2012).
3. Prioritization means that de-prioritization has also to occur which results in exclusions of cover for some programmes. The dynamics of removing well-established health interventions are very different from those of introducing new ones and have received little attention although this is beginning to be rectified (Elshaug et al. 2007; Garner et al. 2013). The process of limiting access to interventions (either stopping old or restricting new) makes the process a political one with all that that implies.
4. There is a tendency to separate out components of healthcare; for example, emerging technologies are assessed separately from chronic disease management which is separate from primary and community care and all are separate from public health initiatives. This separation not only occurs in the context of planning and delivering services but also most importantly in budgetary management making prioritization complex with the result that often no one has overall responsibility for a coherent approach to priority setting.

So, although many of the challenges are common, healthcare systems in various national settings will make different decisions about priorities, differences based on the distinctive balance of social values in each country, as well as their particular methods for capturing and incorporating values in decision-making. These differences will also reflect the level of economic development of each country, its institutional arrangements for deciding on healthcare priorities, the balance of power between competing social groups within the decision-making system, and the distinctive civic culture that prevails. It is this combination of common challenges, encompassing both management challenges and ethical challenges, and distinct institutional and cultural differences, that makes the cross-national comparative study of social values and health priority setting so important to understand. Before systems can learn lessons or even exchange experiences with one another, they first need to locate the social value challenges in their specific circumstances.

A new approach: 'values-based' prioritization

We have suggested so far that all healthcare systems face common problems of priority setting, and that more attention needs to be paid to the way in which the social values of different societies condition the way in which those priority-setting decisions are made. If we are to go beyond this generalization, we need to identify more systematically what the key social values are that are relevant to priority setting. Identifying such values is potentially a large data-gathering task. However, as a way of seeking to answer this question, we convened, in February 2011, participants from seven countries in London, United Kingdom, with a follow-up meeting in Rio de Janeiro, Brazil, in June 2011 to discuss the issues. The starting point for the discussion was the creation of a draft template (see Table 3.5.2) for assessing the role of social values in healthcare priority setting in each country, the object of the template being to detail the logical pattern of such values (Clark and Weale 2012).

What emerged from the workshops was a view that procedural values like transparency, accountability, and participation play an important role in policy deliberation in different contexts alongside substantive values like clinical effectiveness, cost-effectiveness, justice (also sometimes called equity), solidarity, and autonomy.

There are potentially a large number of content values, but five seem to dominate the current approaches to priority setting—clinical effectiveness, cost-effectiveness, justice/equity, solidarity, and autonomy. That list draws upon a reading of statements of social values from NICE (Rawlins and Culyer 2004; NICE 2008) and from the wider bioethics literature (Cookson and Dolan 2000; Hoedemaekers and Dekkers 2003; Oliver 2003; Powers and Faden 2008; Chalkidou et al. 2009; Persad et al. 2009).

The process values selected—transparency, accountability, and participation—are those commonly associated with processes of public reasoning and legitimacy in democratic decision-making (for example, see Gutmann and Thompson 2004). They also draw on the values inherent in what has become the leading framework for procedural justice—Daniels' accountability for reasonableness model (Daniels 2000)—and on the values adhered to by NICE in its decision-making processes (NICE 2012).

Table 3.5.2 Description of content and process social values

Content values	Meaning, purpose, and values-based questions
Clinical effectiveness	<ul style="list-style-type: none"> • Meaning: the ability of a procedure to accomplish a given clinical purpose. Commonly considered to imply that a given treatment is better than existing alternatives because it provides greater health benefits. • Purpose: to secure patient safety and to ensure that resources are not wasted on ineffective or harmful interventions. • Values-based questions: how <i>much</i> benefit has to be achieved for an intervention to be classed as clinically effective? This can be a matter of value judgement, rather than scientific evidence.
Cost-effectiveness	<ul style="list-style-type: none"> • Meaning: an intervention is cost-effective if the difference in costs between it and alternative interventions can be justified in terms of the health benefits it produces. • Purpose: to secure value for money in terms of ensuring that the <i>most</i> health benefits are obtained from available resources—does this by assessing opportunity costs. • Values-based questions: QALYs might be impartial, but can health states and health benefits produced by different treatments be valued objectively in this way? Does cost-effectiveness focus too much on capacity to <i>benefit</i> from interventions rather than on the <i>need</i> which exists for them?
Justice/equity	<ul style="list-style-type: none"> • Meaning: there are many conceptions of justice, but one meaning common to all is that like cases should be treated as like and unlike cases as unlike. In the case of healthcare, likeness will be that of patients' conditions. • Purpose: seeks to ensure an equitable distribution of resources wherein only those factors which are morally relevant to healthcare are taken into account, and that morally <i>irrelevant</i> considerations are excluded. • Values-based questions: determining what counts as a 'morally relevant factor' is highly arguable—to what extent are, for example, age, personal responsibility, economic, or health inequality morally relevant or morally irrelevant factors when determining priorities in the allocation of healthcare resources?
Solidarity	<ul style="list-style-type: none"> • Meaning: all members of society will stand together and will support those who are worst off either in health or in financial terms, depending on the particular form of solidarity espoused. • Purpose: to ensure that no member of society is denied healthcare because of financial barriers to access, and to improve the lot of the worst off (either the sickest or the poorest) in society. • Values-based questions: given the pressures of demography and high-cost pharmaceuticals on available resources, how far do the limits of solidarity stretch?
Autonomy	<ul style="list-style-type: none"> • Meaning: many conceptions, but one meaning common to all is the ability of individuals to be self-directing and to make decisions for themselves about important matters, including healthcare. • Purpose: to secure certain freedoms for the individual to choose the form of healthcare they might prefer and, in some conceptions, to confer responsibility upon the individual for those choices. • Values-based questions: to what extent is it desirable—or possible—to foster individual autonomy in circumstances of limited budgets, where doing so can have negative consequences for justice and for collective healthcare choices?
Process values	
Transparency	<ul style="list-style-type: none"> • Meaning: making both the content and the process of decision-making visible and comprehensible to all relevant parties. • Purpose: making decision arrangements as transparent as possible allows stakeholders—from patients to politicians to clinicians—to evaluate how decisions have been arrived at and thereby increases the chances of decisions being viewed as legitimate, especially by those who lose out. • Values-based questions: what does genuine transparency require, given that the mere transfer of information will not necessarily enable stakeholders to comprehend or evaluate decisions?
Accountability	<ul style="list-style-type: none"> • Meaning: one party justifies and takes responsibility for its activities to another party. Being accountable in priority setting means having the obligation to answer questions regarding decisions about which interventions are prioritized and why. • Purpose: at one level, to ensure that those who are responsible for decisions are able to provide justifiable reasons for priority setting to those affected—especially to those who lose out—and to taxpayers or insurance payers for how their money is spent. • Values-based questions: how to secure meaningful accountability? How much accountability might be too much?
Participation	<ul style="list-style-type: none"> • Meaning/purpose: to allow different interests to contribute and have their voices and experiences heard—thereby contributing to the quality, legitimacy and democratic validity of decisions. • Values-based questions: how best can we capture what is morally and politically important about engaging the public and other stakeholders in priority setting decisions? Who should be involved? And by what methods is genuine, democratic participation best secured?

The content of decision-making

Clinical effectiveness

The clinical effectiveness of a health intervention refers simply to the quality of the benefits it provides for patients. As such, clinical effectiveness is a fundamental value in priority-setting decisions, given that it is clearly undesirable to waste limited resources on procedures that provide low levels, or indeed no benefits to patients or, worse still, that may actually do harm. The positive aim of the principle, then, is to ensure that health benefits are achieved. One way of measuring effectiveness is in terms of the advantage an intervention has over the relevant alternatives, so the benefit or effect of a treatment is the difference it makes to the health state of patients over and above the benefits provided by alternative treatments.

There are some practical issues concerning the principle of clinical effectiveness. There may be different attitudes towards testing of established interventions and innovative ones, with the latter often being subject to much more rigorous standards of effectiveness than the former. Problems can also arise around lack of evidence of effectiveness of new treatments: while it seems entirely proper that clinical effectiveness should be assessed according to the highest scientific standards, this may mean waiting for long periods of time before the effectiveness of a treatment is fully proven. Therefore, questions about how much benefit is required for a treatment to be classed as ‘clinically effective’ often turn on value—rather than purely technical—judgements. Where there is unmet need and no other clinical developments have been available to a particular patient group over recent years, a lower level of benefit might be thought acceptable on grounds that such patients should be offered ‘something’, even if the clinical effectiveness of that ‘something’ is lower than might ideally be sought. The simple fact that ‘something is being done’, even if it only provides a small or uncertain benefit, may be very important (Clark and Weale 2012).

Cost-effectiveness

The aim of cost-effectiveness analysis is to ensure that the *most* health benefits are obtained from limited resources. Cost-effectiveness seeks to establish whether differences in costs between alternative interventions can be justified in terms of the health benefits they respectively produce. As such, opportunity costs are the central concern: comparison between health gained and health forgone is at the heart of the rationale for cost-effectiveness analysis, such that the benefits provided by a treatment for one set of patients must be more than the benefits forgone by not providing a treatment to another set of patients. Further, by using estimates of health benefits and economic costs that are equivalent across treatments, cost-effectiveness evaluation can, in principle, compare the relative worth of healthcare interventions even if those interventions are quite different. QALYs provide a means of doing this (➤ see Chapter 6.6).

Supporters of QALYs point to impartiality as a strength of the approach since a year of life has the same value regardless of whose year of life it is—someone old or young, rich or poor, etc. However, questions arise around the subjectivity of how people value health states. The valuation of health states which inform QALYs can be thought to be problematic because there is no reason to expect that different people, different groups of people, or even the same people at different points in their lives, will value health states in

the same way. Also, it is important to consider *whose* quality of life is judged—just the person with the illness, or that of her family too, given that ill health can have a detrimental effect on the well-being of carers and other family members. Another issue of value judgement in relation to QALYs is their reliance on the conception of need as capacity to benefit. This conception values the *outcomes* of health interventions, rather than the ‘inputs’ to which they respond, and logically entails that the more one can benefit from a treatment, the more one needs it.

As the earlier contrast between the United Kingdom and Germany illustrated, the use of QALYs can be controversial. Some object to the use of QALYs because using them seems to imply that the sole purpose of a healthcare system is to maximize benefit, that is to secure the largest gain in health improvement aggregated over a given population. Taken in this way, the use of QALYs would not accord with important social values. As the example of priority setting in Oregon showed, a simple maximizing approach would mean that a small benefit for a large number of people would outweigh a significant benefit for a small number of people: tooth-capping could be given higher priority than appendectomies. However, using QALYs is not logically tied to a maximizing approach. A QALY is simply a measure of benefit, akin to the disability-adjusted life year (DALY). How those benefits are given priority for any one population depends upon the social values that are relevant to that population.

A second concern in connection with the value of cost-effectiveness is that it is incompatible with asserting a universal right to health (see Chapter 3.3). The idea of the right to health has been an important element in the ‘health for all’ movement and the idea also plays an important role in arguments for universal coverage. To say that cost-effectiveness is important seems to suggest that the right to health should be curtailed when there are insufficient resources—or worse still when governments decide that there are insufficient resources, even though wasteful expenditures may be taking place elsewhere in the public or private sectors. However, this conflict between cost-effectiveness and the right to health is more apparent than real. The right to health has always been recognized as the right to the ‘highest attainable’ level of health, and in this respect resource and cost concerns have always been accepted through the idea of the ‘progressive realization’ of the right to health. Moreover, the principle of cost-effectiveness applies even when universal access to good healthcare has been secured. Indeed, it can be argued that cost-effectiveness is highly important within systems that secure universal coverage, since avoiding the distorting effects of low value interventions enables more to be done for everyone.

Justice

The value of justice or fairness is fundamental to priority-setting decisions and, in terms of its inclusion in the list, perhaps the least controversial. It is, however, one of the most contested values not only in priority setting but in bioethics and indeed political philosophy more widely, with multiple models available (see Hoedemaekers and Dekkers (2003) for a summary of dominant conceptions of justice and their application to healthcare). One notion is common across very many of these models however: this is the principle that like cases should be treated as like and unlike as unlike. In decisions about healthcare, the most obvious condition of likeness of patients is likeness of their illness: so it

is equitable for two people who have cancer to be treated similarly—the relevant characteristic here is having cancer. Irrelevant characteristics to take into account in this situation might be the gender or ethnicity or sexual orientation of the patients: to base priority-setting decisions on these considerations would be unjust because they make distinctions between persons which are irrelevant to their health condition. However, it is not always easy to distinguish which characteristics of persons are relevant and which are irrelevant: some have argued that the ‘merit’ of individuals based on judgements about their contribution to society can be taken into account (Mooney 1987; McIntyre and Gilson 2000); others argue that it is fair to provide greater benefits to the young or middle aged rather than to the elderly on grounds that the old have already had a ‘fair innings’ (Williams 1997), or that if people were to prudently allocate resources to themselves, they may do so in a way which favours their young and middle-aged selves who have projects to fulfil or dependants to care for (Daniels 1988). Arguments of principle also abound as to whether personal responsibility for health states should influence resource allocations (see Cappelen and Norheim 2005). Further questions arise over the justifiability of according special priority to particular health needs—for example, to different kinds of diseases, to care at the end of life or to curative over preventive interventions.

Some conceptions of justice can justify weighting some considerations more heavily than others if they are concerned with redressing health inequalities. A concern with these inequalities may lead to according public health interventions greater priority—for example, to targeting interventions at those with co-morbidity factors, or focusing resources on preventive rather than curative interventions in order to tackle health inequalities at the outset, where they are related to socioeconomic background. Further, the idea of justice also applies to how healthcare is financed—notably, the effect that different systems of financing have on social or health-related inequalities, for example, the potentially catastrophic levels of expenditure incurred in countries where health-related costs have to be met by individuals paying direct, out-of-pocket charges for treatment.

Overall, how fairness in healthcare is conceived in different systems will naturally be shaped by wider conceptions of social justice, which may in turn be affected, for example, by levels of social inequality and attitudes to discrimination, as well as by social institutions such as written constitutions or bills of rights. Which conception of justice or fairness is in operation will also be substantially informed by the balance of the other social values in the list.

Solidarity

Solidarity is a value which can be particularly influential in shaping conceptions of justice. The principle of solidarity implies a commitment to the idea that all members of society will stand together and will not leave anyone behind, no matter how needy or disadvantaged. However, solidarity can take different forms: it can take a contractual form, such as membership of a welfare state or of a basic healthcare package, where it is primarily expressed through a willingness to share the financial risks of ill health, or a more generalized humanitarian form which is expressed in decisions which give priority to those who are worst-off in health terms. As such, the principle can be manifested either in concern about the negative effects of healthcare financing overall or in the process

of priority setting. The two forms of solidarity converge on the issue of cost-sharing or co-payment, particularly in systems which are mainly publicly financed: given the limits of funding in these systems, some element of cost-sharing is often present so that the state pays for some aspects of healthcare, and the individual for others. In privately financed systems, decisions have to be made as to what interventions will be funded by insurance premiums, and what levels of ‘excess’ individuals are left to pay themselves. The effect of a decision to make a certain intervention the subject of a co-payment—that is, a private payment by the individual—is to put that intervention beyond both the bounds of financial solidarity and health solidarity (Weale and Clark 2010). The relevant intervention may be either so expensive (whether clinically effective or not) as to impose an unjustified burden on the pool of risk-sharers, or its benefits may be either sufficiently uncertain and/or trivial for it to be justified in terms of health solidarity. The value of solidarity is also highlighted in responses to the tension between the principles of medical need and cost-effectiveness, and in how those principles are ordered. Where humanitarian solidarity is valued particularly highly, medical need may be prioritized over all other considerations, including cost-effectiveness. This has been the case in Sweden where, although scarce resources have called for cost-effectiveness considerations to be taken into account in priority setting, such is the social and political commitment to solidarity in the form of meeting medical need that issues of cost-effectiveness are sidelined.

However, the way in which demography, the increase in chronic diseases, and the high cost of pharmaceuticals are combining in many countries is increasingly putting strains on solidaristic healthcare arrangements, and raising questions as to where the reasonable limits of solidarity might lie. In such circumstances, attention may turn to the value of individual autonomy as decision-makers reflect on the possibilities for increasing personal responsibility either for health states or for healthcare financing, in order to ease pressure on the public purse.

Autonomy

The value of autonomy has a varied set of meanings (see Feinberg 1986) but it is often used to refer to the ability of individuals to be self-directing and to make decisions for themselves about important matters. Indeed, it is often taken to be one of the fundamental principles in medico-moral decisions, along with requirements of beneficence, non-maleficence, and justice (Beauchamp and Childress 1989). However, autonomy can be instrumental not only at the clinical level but also at the macro level of policy decisions about priority setting, both in terms of questions about individual responsibility for one’s own health and in terms of questions about individual freedoms, perhaps most notably the freedom to choose the form of healthcare one prefers—and the responsibility that goes with that freedom to pay for those choices with one’s own money (see Richards (2008) and Weale and Clark (2010) for examples of this conception of autonomy). Market-based approaches to healthcare tend to value autonomy more highly than other, notably solidarity-based, approaches. This might affect how priorities are set in a number of ways: it might be thought best that individuals are left to decide individually about how they spend their money and what healthcare goods and services they choose to purchase, and so perhaps only the most severe and urgent medical needs will be prioritized for public funding, with the rest

being met either by insurance premiums or ad hoc out-of-pocket expenses. As we have already seen, there will likely be negative implications for justice from such an approach. When health-care priorities are set collectively, decisions may perhaps ignore what matters to some individuals with regard to their own medical need and treatment preferences. Where a healthcare budget is limited, giving full scope to individual self-determination will lead either back to collective healthcare choices in order to secure economies of scale or to long waiting lists—and there is arguably little self-determination to be pursued while one sits on a waiting list. However, it is possible to conceive of ways in which greater individual autonomy could be secured without necessarily leading to negative effects on justice. Priorities could be set so that aspects of care which are not central to clinical effectiveness are left to the individual to select and make the appropriate ‘top-up’ payment—for example, around different standards of accommodation in hospitals or around medically ‘unnecessary’ treatments. However, this runs into problems of defining what is medically necessary, and how apparently marginal factors like different standards of hospital accommodation can affect patients’ overall levels of well-being and their recovery from interventions. So, while they might be ‘strictly’ irrelevant from the perspective of the values of justice and effectiveness, it is not clear that this can be guaranteed in practice with real human individuals.

The process of decision-making

There has been increasing emphasis over recent years on the importance of procedural values in priority setting, partly in recognition of the significance of the quality of policy processes to the public legitimacy of decisions. As norms of democratic legitimacy are diffused around the world, so the values of transparency and accountability become more important. However, given that the content values are themselves subject to dispute, some way has to be found procedurally of dealing with the plurality of perspectives that this implies. As Daniels has commented, ‘establishing a fair process for priority setting is easier than agreeing on principles’ (Daniels 2000). In this context, three values are particularly important: transparency, accountability, and participation.

Transparency

The value of transparency has both normative and practical purposes (Clark and Weale 2012). Where people lose out as a result of priority-setting decisions it may be thought important, as a matter of principle, that they are able to see that both the reasons upon which such a decision is based, and the processes involved in reaching it, are fair. The instrumental value of transparency is also related to this ability of all interested parties to see the fairness of decisions: in this way, trust in decision-makers is increased, and clinicians, patients, and the public are left in a better position to accept priority-setting decisions as fair even (and especially) for those who may lose out—if they can see that those decisions are based on appropriate and relevant reasons.

Transparency in decision-making is often associated with explicit priority setting, where reasons and criteria are openly stated, and where it is clear who makes the decisions and how they do so. Contrary to this, implicit priority setting, where decision-makers, decision protocols, and criteria are not openly stated, tends to obscure decision processes from public and patient scrutiny: what is not known cannot be challenged or criticized,

and those who do what is not known are themselves not known, and so cannot be held responsible. As such, implicit priority setting may hinder public understanding and acknowledgement of the real limitations that exist with regard to resources in health-care. While the demand for transparency might arise most in the context of publicly funded systems where it is necessary as an element of democratic accountability, it is also relevant in privately funded systems: that is, when private providers claim to be providing a benefit for which they should be fairly recompensed by funders of either a public or private nature, that claim should be capable of being openly demonstrated to all interested parties.

Biron et al. (2012) drawing upon O’Neill (2002) and Rid (2009), have argued that the mere disclosure of information will unlikely be sufficient for transparency. Simple disclosure does not ensure that information will be intelligible to the public but may instead simply provide a ‘flood of information’, causing a great deal of uncertainty in the public mind. However, in many societies the problem is more likely to be too little information rather than too much. In the People’s Republic of China, for example, where the World Bank estimates that there are some 750,000 premature deaths through pollution, levels of soil pollution are not made publicly available (Hook 2013). Just as there should be transparency in respect of public health risks, so there should be transparency in respect of priority setting decisions, no matter how demanding the task may seem.

Accountability

Accountability occurs when one party to the decision-making process justifies and takes responsibility for its activities to another. Being accountable in health priority setting means having the obligation to answer questions regarding decisions about which interventions are prioritized and why. We can think of accountability in terms of three questions: ‘Who?’, ‘What?’, and ‘How?’ (Clark and Weale 2012). The answers to each of these questions will vary considerably depending on the nature of the health system in question.

In terms of ‘Who?’ we can ask both who is held accountable, and who does the holding to account—who should answer the accountability questions and who should ask them. Those who should answer the questions will be those who make the decisions: for example, central or local government, civil servants, health professionals, medical institutions, or insurers. Pharmaceutical companies may also have an important role in influencing decisions and there may be good grounds for holding them to account too. There is a range of possibilities as to who asks accountability questions: patients, the public, and health professionals most obviously, although the courts have also become important actors in holding decision-makers to account in some countries, and in privately financed systems, employers and individual payers will likely be those who ask questions of insurers.

The ‘What?’ question, we might phrase as ‘Accountability for what?’. The main answer to this in publicly funded systems has traditionally been the spending of taxpayers’ money. In privately funded systems, financial accountability is also primary: private and corporate payers will want to ensure that their money is being used responsibly. However because decisions about priority setting involve value judgements as well as purely economic ones, so financial accountability alone does not provide a comprehensive answer to accountability questions. Accountability around value

judgements can be difficult to assign however, since even where priority setting is explicit in economic terms, it may not be so in respect of social values.

With regard to the ‘How?’ question, two general types of accountability can be identified. The first type is simply about providing information on decisions and implies a one-way transmission of information from decision-makers to, for example, the public. The second type of accountability moves beyond simple reporting of decisions and attends not just to what was decided but to the reasons for decisions, often in the form of a two-way dialogue. This can help build trust in decision-makers by signalling that they are interested in the views and well-being of patients and the public. In this way, the value of accountability is complemented by the value of participation.

As even this brief discussion suggests, discharging the obligation of accountability can be complex and demanding. It requires decision-makers to assemble the relevant information and provide a chain of reasoning from evidence to policy that a variety of audiences can follow. Concerns have also been raised that an emphasis upon accountability can descend into mere formal compliance in the form of a ‘box-ticking’ culture rather than a commitment to communicating the reasons for decisions (O’Neill 2002). Of course, this is always a possibility, and where top-down (and often poorly thought out) performance targets are used, the risk is increased. However, there is no reason to believe that this sort of distortion is intrinsic to the practice of accountability, which is a value that plays an important role in the public justification of priority-setting decisions.

Participation

Participation refers to the opportunity that those affected by public decisions have to contributing towards the formation of those decisions. One primary reason why participation is a value is because it can allow different interests to contribute and have their voices heard. This is important for several reasons. Firstly, because prioritization decisions are fundamentally value judgements—and value judgements inevitably vary between individuals and groups within society—having those individuals and groups participate in decision-making is likely to help make both the process and the outcome more legitimate and more likely to be accepted, especially by those who lose out. However, including different viewpoints in the decision-making process can also improve the quality of decisions, given that it widens the range of information taken into consideration: for example, patients can make important contributions to the technical quality of decisions via their direct experience of pharmaceuticals. Participation in the decision-making process is also a mechanism for engaging powerful constituencies in a constructive manner—for example, leaders of the medical profession—as well as for improving the transparency and sharing accountability for decisions. However, within democracies, there is a deeper reason for participation: it is commonly thought that citizens should be able to participate in decision-making about issues that affect their vital interests—and access to appropriate healthcare is clearly one of the most important of such interests. Healthcare priority setting, then, is an obvious candidate for a democratic mandate.

The most obvious answer to the question of who should participate is ‘patients’—the people directly affected by priority-setting decisions. However, the patient perspective is not the only relevant

one: it has been argued that the perspective of the citizen should also be engaged in order to gain a wider and more inclusive view of the issues. Engaging only patient groups can exclude those who are not current users but who may use the services in the future, and the narrow perspective of a patient who has a particular personal interest in a service may conflict with the broader, longer-term interest of a citizen who is a taxpayer, a voter, and a member of any number of communities. There is an increasing tension in some healthcare services between the push to increase individual rights and ‘consumer interests’ in healthcare and the need to make collective decisions which are in the interests of the citizen and the wider community (Montgomery 1996).

Process and content

How do these process and content values relate to one another? Although transparent and accountable processes are necessary to make resource allocation decisions in ways that are justifiable, we should not assume that process alone will be sufficient (Powers and Faden 2008). This in turn raises the question of whether there is a cultural bias in supposing that some content values are always relevant to ethically justified priority setting. Does justice in China, Thailand, Korea, Colombia, Germany, or the United Kingdom mean the same thing? The short answer is that we do not know until we see their priority-setting processes develop and decisions are made. However, it is striking that as countries like China, Korea, and Thailand develop, they have moved towards policies based on the principle of universal access, in that respect at least following the European model.

A similar question can be raised about process values. Can fair priority-setting decisions be reached in contexts where procedural values are not considered to be particularly important or necessary? Again, the answer to this question must remain open. However, we should always bear in mind that those who say that certain process values associated with transparency and accountability are culturally specific risk underestimating the extent to which there is a willingness to protest where standards of openness are not met. As our earlier example of pollution in China showed, the demand for greater transparency is widespread where there is a threat to human health.

One special case where we might observe difference in social values is in the importance attached to public participation as compared to expert judgement.

A recent study of priority setting in eight different countries notes that many countries without widespread public involvement in decision-making have achieved priority-setting objectives that are largely accepted by the public. In Norway, for example, ‘the recommendation was that this process [of decision-making] should be expert-driven, and not involve much public debate’ (Sabik and Lie 2008). Yet, there is also a complex interplay between the value and technical components of health priority-setting decisions as well as between the values themselves. Different conceptions of the values of justice and solidarity in particular are significant in how technical judgements are worked out and how the various reasons within decisions are weighted. The degree to which a society values solidarity will have a large impact on how it weighs justice considerations in decisions, and what form those considerations take, particularly in determining which characteristics of persons are relevant—and therefore legitimate—to take into account in priority-setting decisions and which are not. As such,

a purely technical approach to quality of life measures that does not acknowledge the values it assumes will likely be lacking in some way—and it will make accountability for, transparency and participation in those value judgements difficult if not impossible. The Oregon priority setting experiment where a ranked list of interventions was produced on the basis of cost-effectiveness alone, produced considerable counter-intuitive effects (Hadorn 1991) and further, there is evidence to suggest that the public in some countries at least wish for both accountability and participation in relation to value judgements.

Important values underlie both the ‘process’ and ‘content’ elements of decision-making in health priority setting. The ‘process’ values of transparency, accountability, and participation are closely linked: transparency forces governance to be more careful so as to stand up to public scrutiny. In this way, it is the instrument of accountability and justifiability: if transparency is lacking, it will be difficult for decision-makers to be held accountable in any meaningful way since those who wish to hold them to account will not have the relevant knowledge with which to do so. One way to advance transparency may be to increase participation, especially in an area like health where citizens (as well as patients) are directly affected by decisions and where they may have much to contribute to governance. In turn, increasing participation may be a pre-condition to increasing transparency. In terms of ‘content’, value judgements are often hidden in technical criteria such as clinical and cost-effectiveness measures.

A research programme

If almost all decisions in health priority setting involve complicated issues of social values, they are nonetheless often only implicit and unrecognized by policymakers. There is often a sense of ‘muddling through’ when it comes to social values. The challenge of values is demanding, but the capacity to address it when there are many other challenges may be limited, given the complexity of the values-based issues and the unfamiliarity of policymakers with them. This practical need for greater understanding of the role and significance of social values in health priority setting became apparent to the authors and all of those present at the international conference held in London in early 2011. A new research programme was finally launched at the HTAi conference in Bilbao in 2012.

This new research programme (see <http://www.ucl.ac.uk/socialvalues> for further details) (Littlejohns et al. 2012b) has as its central focus an international comparison of the role that social values play in the setting of healthcare priorities in Thailand, Korea, Columbia, the United Kingdom and the United States. It requires the collection of complex data from a variety of agencies in the different countries. The research will be carried out through a network of policymakers and researchers, and will involve a cross-national comparative empirical analysis of priority setting together with policy evaluation informed by recent developments in normative political theory, culminating in the production of a decision tool aimed to help policymakers integrate social values considerations more easily and effectively into their decision-making processes.

Two main questions are at the heart of the research programme. What role *do* social values play in decisions about health priority setting and how are they currently taken into account by

policymakers? And what role *should* social values play and how *should* they be taken into account by policymakers?

One distinctive approach to these questions is the use of case studies to provide insight into the challenges of priority setting and into the role that social values play in priority setting decisions. As an ‘inductive’ research tool, they offer a focus for gathering rich information about particular instances of social values issues in ‘real life’ priority setting and, as such, they facilitate comparative research. And for policymakers, case studies offer a means of accessing the experiences of others facing similar problems and provide an opportunity for shared learning. An online ‘catalogue’ of case studies is currently in development as part of the research programme, and uses a standardized reporting template to enable comparison.

However, the ultimate aim of our research programme is not only to improve understanding of the role that social values do and should play in health priority setting, but to translate our findings into a usable tool for policymakers as they confront questions of value choice. The challenge here is to develop a comprehensive, easily usable, and policy-relevant tool which provides a way for policymakers systematically to identify and consider the social values which are involved in their decisions. This is a question of translational research involving the validation of the tool through developmental work with policymakers and other stakeholders. Improving decision-making in the light of important social values is a collective enterprise, and we are sure that many others will be involved in the challenges that are set us all.

Health policy in developing countries

Miguel Angel González-Block, Adetokunbo Lucas, Octavio Gómez-Dantés, and Julio Frenk

Introduction to health policy in developing countries

Most developing nations are making important strides towards better health and universal health service coverage through policies that are increasingly influenced by international experience. The flow of financial resources is also expanding rapidly thanks to the role that health investments are playing in the wider strategy towards democracy, economic growth, and global security (Brown et al. 2001; Hecht and Shah 2006; Frenk and Gómez-Dantés 2007). Health policy in the South is thus increasingly being influenced by globalization, both by responding to global threats and by doing so through extensive use of the pool of global experiences.

Health policy has been critical for the diffusion of life-saving technologies and knowledge that are behind the drop in disparities in life expectancy across rich and poor countries at least since the middle of the last century. Taken as a group, the poorer countries have seen gains of about 5 years on average per decade since 1960, against half this much by the better-off. Critically, the pace of technology diffusion has been more influential for health than changes in the levels of income. Increased access to knowledge and technology thanks to appropriate health policies has accounted for perhaps as much as two-thirds of the 2 per cent per year rate of decline in under-5 mortality rates (Jamison 2006).

However, health policy still has important challenges in a world saddled with conflict, poverty, and the pandemic of HIV/AIDS. In some African countries, the trend in the mortality rate for children under 5 has been reversed. While, between 1960 and 1990, African countries made substantial progress in reducing this rate, in many countries this effort was slowed down considerably, and in some others mortality even rose between 1990 and 2002 (United Nations Children's Fund (UNICEF) 2004).

In this chapter we review the context in which health policies are being developed in low- and middle-income countries. We discuss several key concepts associated with health policy, and describe some of the tools available for policymaking. In the first part, we discuss the role of health policy as a stewardship instrument and the general context in which health policies are being designed and implemented in developing nations. In the second part, we describe some of the novel tools available for policymaking, including burden of disease, national health accounts, and

health system performance assessment. We discuss the increasing international financing for healthcare and the alternatives for achieving universal health coverage (UHC) with financial protection against catastrophic costs of healthcare. We then analyse the search for equity in health and discuss the role of international agencies and health research in the design and implementation of health policies.

The main messages of the chapter are the following:

1. Sound health policies balancing the best evidence, ethical principles, and political realities are needed in developing countries not only to address the pressing needs of infectious diseases and malnutrition and the rapidly emerging problems of non-communicable diseases and injuries, but also the new challenges related to globalization, including pandemics and the health consequences of climate change.
2. Sound health policymaking can contribute to the consolidation of democracy, to economic growth, and to global security. The broad consensus generated around this issue has helped to mobilize *more money for health* in developing nations.
3. Policy-making should be evidence-based, and also results-oriented. Careful planning and skilled management can achieve good results and allow developing countries to deliver *more health for the money*.

Health policy as stewardship

Health policymaking in developing countries is seeking a new model of action to increase health and welfare, largely based on the separation of health system stewardship from service delivery through various forms of decentralization (Bossert 1998; Murray and Frenk 2000). Policymaking is increasingly being envisaged as a stewardship process concerned with attaining trust and legitimacy between a government and its people towards the improvement of the welfare of populations (Londoño and Frenk 1997; Gilson 2003; Bankauskaite et al. 2007; Garret 2007). The *World Health Report 2000* defined stewardship of the health system by national governments as a critical function to realign incentives and to mobilize and allocate resources to achieve the final goals of health gain, financial protection, and responsiveness. Stewardship has also been defined as a function of international agencies to

enable coordination of health systems at the global level (WHO 2000).

Stewardship is an ethically-based, outcome-oriented policy approach and as such it is more interventionist than the economically driven agency approach to state regulation (Table 3.6.1). The notion of stewardship, if properly developed, is also consistent with an evidence-based health policy framework (Saltman and Ferroussier-Davis 2000). A national health strategy based on stewardship can marshal the available evidence to support population-based measures that can improve overall health status. Stewardship capacity is synonymous with the quality of governing institutions within countries, and with the trust that societies place in their governments. In a global climate of increased support for public investments in health, greater attention is being paid to differentiate countries with 'good' and 'stressed' governance in order to marshal international aid support for policymaking.

The process of policymaking for the health sector has become increasingly intricate. Health practitioners, policymakers, planners, and resource providers have to contend with three main issues: *diversity*, *complexity*, and *change*.

There is often great *diversity* within developing countries, as well as between and within different geographical areas. Ecological and geographical factors are recognized as important determinants of health conditions. Economic, social, and cultural determinants also contribute to diversity. The association of poverty, exclusion, and discrimination with poor health status is a consistent finding in both developed and developing countries and has a long research

tradition (Evans et al. 1994). In general, policymaking fails to systematically recognize and act on these determinants. The World Health Organization (WHO) Commission on Social Determinants of Health attempted to redress this shortcoming by creating awareness of such determinants among political leaders and stakeholders, and helping countries adopt comprehensive health and development policies oriented towards them (Irwin et al. 2006).

Complexity in health needs of populations is another challenge. In contrast with rich countries that experienced a substitution of old for new patterns of disease, developing nations are facing a triple burden of ill health: first, the unfinished agenda of infections, malnutrition, and reproductive health problems; second, the emerging challenges represented by non-communicable diseases and injuries; third, the health risks associated with globalization, including the threat of pandemics like AIDS and influenza, the trade in harmful products like tobacco, and other drugs, the health consequences of climate change, and the dissemination of harmful lifestyles. A recent study of risk factors at global and regional levels based on the measurement of burden of disease for 2010 attests to a major shift in risk factors to disease burden, moving away from risks for communicable diseases in children and towards those for non-communicable diseases in adults. According to this study, in much of sub-Saharan Africa the leading risks are still poverty related and affect children (Lim et al. 2012).

Annual changes in mortality projections between 2002 and 2020 suggest decreases in tuberculosis (TB) of over 5 per cent yet increases of between 2.1 and 3 per cent for HIV/AIDS. Diabetes mellitus and road traffic mortality are projected to increase over 1 per cent per year, an alarming rate. In projections to 2030, cardiovascular disease will account for 13.4 per cent of the total world mortality and will rank as the first or second cause of mortality in all income regions (Mathers and Loncar 2006). Tobacco consumption is largely responsible for many disease trends, and particularly ischaemic heart disease. This is a product of relentless push of industry into new, unregulated contexts susceptible to lifestyle changes.

While knowledge and innovative health technologies have been critical in healthcare in developing countries, the explosion of new technologies designed for rich countries as well as innovations of critical importance to the South such as antiretrovirals and Integrated Management of Childhood Illness (IMCI) have markedly increased the *complexity of healthcare*. The expanding scope of prophylactic, diagnostic, and therapeutic options demands an increasing range of specific programmes with the associated need for specialist personnel, new categories of support staff, high-technology equipment, and infrastructure. Fig. 3.6.1 illustrates the complex interaction of medical and non-medical factors that are involved in perpetuating the high maternal mortality rates occurring in the developing world. It also offers clues as to the package of interventions that are required to reduce maternal mortality (McCarthy and Maine 1992). A particular challenge is a renewed tendency to deliver new technologies through vertical programmes that may fail to support the health system while weakening existing programmes (Unger et al. 2003; Molineux and Nantulya 2004; Garret 2007). New approaches to integrate disease control programmes with the health system as to obtain reciprocal benefits are now being proposed and evaluated (González-Block et al. 2012).

Table 3.6.1 Comparison of agency theory and stewardship theory

Characteristic	Agency theory	Stewardship theory
1. Model man	Economic man	Self-actualizing man
Behaviour	Self-serving	Collective serving
2. Psychological mechanisms	Lower order/economic needs (physiological, security, economic)	Higher-order needs (growth achievement, self-actualization)
Motivation	Extrinsic	Intrinsic
Social comparison	Other managers	Stakeholders
Identification	Low-value commitment	High-value commitment
Power	Institutional (legitimate, coercive, reward)	Personal (expert, referent)
3. Situation mechanisms	Control-oriented	Involvement-oriented
4. Management philosophy	Control mechanisms	Trust
Risk orientation	Short term	Long term
Time frame	Cost control	Performance enhancement
Objective	Individualism	Collectivism
5. Cultural differences	High-power distance	Low-power distance

The interaction of medical and non-medical factors in the dynamics of health and disease calls for a critical analysis of needs and opportunities as a basis of designing and managing health programmes. Due to the important influence of non-medical factors on health, it is also necessary to mobilize intersectoral action to complement inputs from the health sector. In this process, policymakers in developing countries should measure their capacity and ensure they first reap their benefits of interventions they can directly control within their health systems (Jamison 2006).

Policymaking in developing countries also has to be fluid and dynamic to adapt strategies and programmes to the many *changes* that are occurring in the environment. Two critical changes are accountability and socioeconomic change.

Global as well as national influences are leading towards greater *accountability* of policymakers to parliaments, provincial stakeholders, as well as to donors, clients, and populations. Decentralization has continued its pace giving provincial authorities and local officials greater autonomy for innovations but also increased responsibility (Hutton 2002; Bossert 1998). Policymaking in the health sector is thus moving from a technical and highly hierarchical approach towards recognizing the role of new actors and processes set in a political and participatory environment.

Changes in the economic and social situation in countries may have a profound effect on the health sector. Health policies have had to be modified in the light of rapid development in some countries and economic recession in others. In the immediate post-Second World War era, macroeconomic policies emphasizing central planning and welfare programmes gained popularity. During the 1980s and 1990s, this trend was reversed, with national policies increasingly favouring free market economy in place of welfare programmes and central control. These changes brought about a slowdown in public health sector investments and the introduction of user fees, without visible improvements (Alliance HPSR 2004). Today, international agencies such as the International Monetary Fund (IMF) and the World Bank have reversed their policies (World Bank IMF Development Committee 2003), and funding has been substantially increased aiming to double the level of international aid to support the Millennium Development Goals (MDGs). Government capacity is being revamped to ensure efficiency and equity in investments.
